Abstract:	As a result of the 2015 refugee crisis, a substantial number of voters experienced a sudden and unexpected influx of asylum seekers in their neighbourhood in the Netherlands. We examined whether and why local exposure to asylum seekers leads to more support for the radical right (i.e. PVV). Our analyses are based on a longitudinal individual-level panel dataset including more than 19,000 respondents (1VOP) who were interviewed just before and shortly after the height of the refugee crisis. We enriched this dataset with detailed information about where asylum seekers were housed from the Central Agency for the Reception of Asylum Seekers. Our empirical study resembles a natural experiment, because some residents experienced an increase in exposure to asylum seekers but similar residents did not. PVV support increased during the refugee crisis and especially among residents who became more exposed to asylum seekers in their neighbourhood.

Format for specific study types

Human Subject Research (involving human participants and/or tissue)

- Give the name of the institutional review board or ethics committee that approved the study
- Include the approval number and/or a statement indicating approval of this research
- Indicate the form of consent obtained (written/oral) or the reason that consent was not obtained (e.g. the data were analyzed anonymously)

Animal Research (involving vertebrate animals, embryos or tissues)

- Provide the name of the Institutional Animal Care and Use Committee (IACUC) or other relevant ethics board that reviewed the study protocol, and indicate whether they approved this research or granted a formal waiver of ethical approval
- Include an approval number if one was obtained
- If the study involved *non-human primates*, add *additional details* about animal welfare and steps taken to ameliorate suffering
- If anesthesia, euthanasia, or any kind of animal sacrifice is part of the study, include briefly which substances and/or methods were applied

Field Research

Include the following details if this study involves the collection of plant, animal, or other materials from a natural setting:

- Field permit number
- Name of the institution or relevant body that granted permission

Data Availability

Authors are required to make all data underlying the findings described fully available, without restriction, and from the time of publication. PLOS allows rare exceptions to address legal and ethical concerns. See the [PLOS Data Policy](#) and [FAQ](#) for detailed information.

Yes - all data are fully available without restriction

A Data Availability Statement describing where the data can be found is required at submission. Your answers to this question constitute the Data Availability Statement and **will be published in the article**, if accepted.

Important: Stating 'data available on request from the author' is not sufficient. If your data are only available upon request, select 'No' for the first question and explain your exceptional situation in the text box.

Do the authors confirm that all data underlying the findings described in their manuscript are fully available without restriction?

Describe where the data may be found in full sentences. If you are copying our sample text, replace any instances of XXX with the appropriate details.

- If the data are **held or will be held in a public repository**, include URLs, accession numbers or DOIs. If this information will only be available after acceptance, indicate this by ticking the box below. For example: *All XXX files are available from the XXX database (accession number(s) XXX, XXX).*
- If the data are all contained **within the manuscript and/or Supporting Information files**, enter the following:

Revision of Manuscript: Exposure to asylum seekers and changing support for the radical right: A natural experiment in the Netherlands

Dear editor,

Please find enclosed our revised submission to ***PLOS ONE*** titled, “Exposure to asylum seekers and changing support for the radical right: A natural experiment in the Netherlands”.

As requested, we have uploaded the minimal anonymized data set necessary to replicate our study findings as Supporting Information files. We also made a complete replication package (website) hosted from GitHub:

<https://jochemtolsma.github.io/ExposureASC2020/>.

Our study is a quantitative study on changes in support for the radical right in the Netherlands against the background of the 2015 refugee crisis. As a result of this refugee crisis, some voters experienced a sudden influx of asylum seekers in their neighbourhood and others did not. To evaluate the impact of local exposure to asylum seekers on support for the radical right we use a large-scale individual-level panel survey enriched with detailed information about where refugees were housed from the Central Agency for the Reception of Asylum Seekers (COA). We find that especially among residents who became more exposed to asylum seekers in their neighbourhood, support for the radical right increased.

We have chosen to submit our manuscript to ***PLOS ONE*** because we believe the topic of our research, the impact of the 2015 refugee crisis on support for the radical right, may be of interest for a broad multi-disciplinary audience.

I will serve as the corresponding author for this manuscript. I have assumed responsibility for keeping my co-authors informed of our progress through the editorial review process, the content of the review, and any revisions made.

Sincerely,

Jochem Tolsma

Exposure to Asylum Seekers and Changing Support for the Radical Right: A Natural Experiment in the Netherlands

As a result of the 2015 refugee crisis, a substantial number of voters experienced a sudden and unexpected influx of asylum seekers in their neighbourhood in the Netherlands. We examined whether and why local exposure to asylum seekers leads to more support for the radical right (i.e. PVV). Our analyses are based on a longitudinal individual-level panel dataset including more than 19,000 respondents (IVOP) who were interviewed just before and shortly after the height of the refugee crisis. We enriched this dataset with detailed information about where asylum seekers were housed from the Central Agency for the Reception of Asylum Seekers. Our empirical study resembles a natural experiment, because some residents experienced an increase in exposure to asylum seekers but similar residents did not. PVV support increased during the refugee crisis and especially among residents who became more exposed to asylum seekers in their neighbourhood.

Keywords: populist radical right; asylum seekers; natural experiment; ethnic threat; interethnic contact

Introduction

An unprecedented refugee crisis unfolded in Europe over the course of 2015, which brought about political turmoil in many countries. In this study we take a closer look at changes in support for the radical right in the Netherlands against the background of a large influx of asylum seekers in that year. As some people witnessed an influx of asylum seekers in their residential neighbourhood, while others did not, the 2015 European refugee crisis is an interesting case to study the impact of local demographic changes on voting intentions for the radical right.

In 2015, the twenty-eight member states of the European Union together with Norway and Switzerland received more than 1.3 million applications from asylum seekers (Eurostat, 2016). This has been, by far, the highest annual number of asylum seekers recorded in Europe since World War II (OECD 2015). The majority of the asylum seekers that arrived in Europe in 2015 came from Muslim-majority countries. In the Netherlands – the current site of study – more than 40,000 asylum seekers (255 applicants per 100,000 inhabitants) entered the country in 2015, a historical record. The centre-left (PvdA) and centre-right party (VVD) forming the Dutch government fiercely debated the development of a strategy for dealing with these asylum seekers. The refugee crisis not only evoked divergent reactions among Dutch politicians but also among the broader public. The Dutch people made their voice heard, both in support of and in opposition to the arrival of asylum seekers. While the Netherlands Red Cross saw their stock of temporary volunteers grow from 6,000 to more than 36,000 (The Netherlands Red Cross 2015), public demonstrations against the arrival of asylum seekers also intensified over the course of 2015. Especially in communities where new asylum seeker centres (ASCs) were established, people uttered their disapproval by, for example, hanging banners on the assigned buildings with anti-refugee slogans, such as ‘Own people first’.

In this study, we take advantage of a large-scale longitudinal individual-level panel dataset to examine changes in support for the radical right against the background of the sudden arrival of asylum seekers in the Netherlands. In particular, we are interested in whether voters changed their intentions to vote for the radical right after having experienced an inflow of asylum seekers in their residential neighbourhood.

The *Partij voor de Vrijheid* (Party for Freedom; PVV) was in 2015 the only radical right party in the Netherlands with seats in Parliament (Bakker *et al.* 2015; Immerzeel *et al.* 2011). The PVV was founded in 2006 and since then led by Geert Wilders. The PVV is known for its anti-immigration statements and its campaign to ‘de-Islamize’ the country. During the refugee crisis, the PVV started targeting (Muslim) asylum seekers in its political discourse. Wilders

announced in October 2015 the launch of a website where people can report complaints about asylum seekers (PVV, 2015). During new year's eve 2015, mass sexual assaults took place in Cologne, Germany. Relatively many of the identified suspects were asylum seekers (Connolly 2016). Wilders subsequently propagated that all male asylum seekers should be locked up (Sims 2016). The PVV is, therefore, an attractive party for voters with (strong) anti-migration, anti-Muslim and anti-asylum seeker attitudes.

The ethnic composition of people's living environment is a focal point in scholarly attempts to explain the popularity of radical right parties (e.g. Coffé *et al.* 2007; Edo *et al.* 2019; Green *et al.* 2015; Lubbers and Scheepers 2002). In the Netherlands, support for the radical right among native-Dutch is more common in neighbourhoods where more non-western migrants (and their descendants) live (e.g., Janssen *et al.*, 2019; Savelkoul *et al.* 2017). Yet, war refugees are clearly a distinct group compared to immigrants who enter destination countries such as the Netherlands as a result of union formation, family reunification and labour migration. It is likely that, in general, war refugees are considered to be more deserving to enter and stay in receiving countries (cf. Bansak *et al.* 2016) and that they may therefore provoke less opposition.

Having said that, previous research has shown that a larger influx of asylum seekers is positively related with more support for the radical right (e.g. Arzheimer 2009; Kessler and Freeman 2005; but see also Arzheimer and Carter, 2006). However, studies addressing this relationship are largely restricted to the country-level and generally draw on cross-sectional data collected before the 2015 European refugee crisis. Research addressing the influx of asylum seekers in local residential areas and its consequences for people's voting intentions is scarce. Dustmann, Vasiljeva and Damm (2019) showed that the allocation of larger refugee shares in Danish municipalities in the 1980's and 1990's was related with higher vote shares for anti-immigration parties. Dinas and colleagues (2019) demonstrated that the massive but transient inflow of refugees on Aegean islands during the 2015 European refugee crisis fuelled support for the extreme-right on these islands. Besides focusing on relatively large geographical units, both studies employed a macro-level approach – i.e., focusing on vote shares, rather than individual voting intentions and changes thereof over time – which does not allow to empirically assess underlying mechanisms for this relationship.

In this study, we aim to contribute to earlier research in two ways. Taking advantage of individual-level longitudinal panel data, we will first examine whether Dutch voters who have been exposed to a sudden and unexpected influx of asylum seekers in their local neighbourhood are more (or less) likely to *change* their voting intention to the PVV than voters who have not

96 been exposed to an inflow of asylum seekers in their neighbourhood. Second, we aim to explain
97 any observed relationship between the influx of asylum seekers in the neighbourhood and
98 support for the radical right.

99 A positive relationship between the two phenomena may be explained by the threat
100 mechanism (e.g. Blalock 1967; Coser 1956; Quillian 1995) stating that an increasing ethnic
101 outgroup size fosters feelings of economic and cultural ethnic group threat, and consequently,
102 anti-immigration attitudes which are the central attitudinal driving force behind support for the
103 radical right (e.g. Ivarsflaten 2008; Rydgren 2007). At the same time, residential proximity to
104 ASCs may lead to contact with asylum seekers (Blau 1994). Positive intergroup contact
105 stimulates interethnic tolerance (Allport 1954; Pettigrew and Tropp 2011), which can be linked
106 to lower levels of support for the radical right. The few, cross-sectional studies putting both
107 mechanisms to the test, found support for both the threat and the positive contact mechanism,
108 albeit weaker for the latter (Green *et al.* 2015; Rydgren 2008; Savelkoul *et al.* 2017). We are
109 the first to test both the threat and positive contact mechanisms simultaneously from a
110 longitudinal perspective, using individual-level panel data in the context of the refugee crisis.

111 To reach these aims, we employ a longitudinal and sizeable panel dataset on individual
112 respondents (N>19,000; 1Vandaag Opinion Panel Survey). Our panel dataset allows us to
113 control for (time-stable) unobserved heterogeneity. We enriched this micro-level data with
114 detailed information about where asylum seekers were housed from the Central Agency for the
115 Reception of Asylum Seekers (COA). Formally, the term ‘asylum seeker’ refers to persons who
116 apply for asylum and seek refugee status. We therefore use this term when we talk about the
117 persons who were housed in the ASCs during the 2015 refugee crisis. We use the term ‘refugee’
118 more loosely to refer to persons fleeing the risk of serious harm and persecution (and who may
119 or may not have an official refugee status).

120 The period in between the two waves of our data (February and November 2015)
121 spanned the period in which the settlement of asylum seekers in residential environments
122 throughout the Netherlands took place. Asylum seekers were unable to select the region where
123 they wanted to be housed. Similarly, neighbourhood residents had no, or only limited influence,
124 in where new asylum seekers were going to be housed and, within the time-window of our
125 study, did not have time to move out of their neighbourhood if they opposed to the inflow of
126 asylum seekers. Selective residential mobility, generally plaguing the neighbourhood effects
127 literature, is thus not an issue. Given the sudden and unexpected influx of asylum seekers, the
128 management of asylum seekers flows was chaotic and haphazard. The placement of asylum
129 seekers was – as we will show below – to a large extent random and therefore our study

resembles to some extent a natural experiment. For these three reasons – individual-level panel data allowing to control for (time-stable) unobserved heterogeneity, no selective residential mobility, increased exposure to asylum seekers (to a large extent) random – we are thus able to make relatively strong causal claims on the impact of the refugee crisis on changing support for the PVV.

Theoretical expectations

According to conflict theories (Blalock 1967; Coser 1956, Quillian 1995), a larger relative size of non-natives in people's living environment induces competition between natives and non-natives for scarce economic resources (e.g. jobs and affordable housing). Conflicting cultural values (e.g. toward homosexuals or freedom of speech), also, become more apparent when the group of non-natives is more sizeable. After reviewing approximately 100 studies of immigration attitudes, Hainmueller and Hopkins (2014) conclude that perceptions of group threat affect immigration attitudes. This holds especially for concerns about the cultural impact of immigration, and not so much the possible consequences of immigration for one's personal (economic) situation. Because earlier research convincingly showed that voters who perceive ethnic minorities as a threat and who hold anti-immigration attitudes are more likely to cast their vote for the radical right (e.g. Green *et al.* 2015; Lucassen and Lubbers 2012; Werts *et al.* 2012), one would also expect to observe a positive relationship between the presence of non-natives in people's living environment and their likelihood to vote for the radical right.

Previous empirical studies reached mixed conclusions when it comes to the relationship between the ethnic composition of people's *local* living environment and their likelihood to vote for the radical right. Whereas several studies provided support for a positive relationship (e.g., Coffé *et al.* 2007; Lubbers and Scheepers 2002; Valdez 2014), others found no significant relationship (Lubbers and Scheepers, 2000) or even a negative relationship (Bowyer 2008; Rydgren and Ruth 2013). For the Netherlands, previous studies showed that support for the radical right is more common in neighbourhoods with a larger share of non-western migrants (Janssen *et al.* 2019; Savelkoul *et al.* 2017; but see also Van Wijk *et al.*, 2020 who found a U-shaped relationship). These studies lack, however, convincing evidence for a threat mechanism. This was due to the fact that outgroup sizes at the neighbourhood level were not consistently linked to more intense feelings of ethnic group threat, a null-finding reported by others as well (e.g. Pettigrew *et al.* 2010; Pottie-Sherman and Wilkes 2017; Schlueter and Wagner 2008).

Olzak (1992) was one of the first scholars who argued that recent substantial increases rather than stable levels of non-natives in people's living environment trigger perceptions of

164 ethnic threat. In line with this idea, several studies provided empirical evidence for a positive
165 relationship between an increase in immigrants and voting for the radical right (e.g., Kessler
166 and Freeman 2005; Lubbers and Scheepers 2000; but see also Lubbers *et al.* 2000). The 2015
167 European refugee crisis provides an interesting case to test the impact of a sudden demographic
168 change on radical right voting. At the country-level, several studies provided support for a
169 positive relationship between the share as well as the influx of asylum seekers and support for
170 the radical right (e.g., Arzheimer, 2009; Kessler and Freeman 2005; but see also Arzheimer and
171 Carter, 2006). Similar relationships have been found at somewhat lower geographic scales
172 (Dinas *et al.* 2019; Dustmann *et al.* 2019).

173 Although asylum seekers in the Netherlands do not directly compete with natives for
174 jobs – they are not allowed to work – they do receive a small allowance and, once they are
175 granted a refugee and permanent resident status, will compete for public housing. This is likely
176 to trigger perceptions of economic threat among natives. Asylum seekers in the Netherlands are
177 not confined to ASCs and are allowed to wander free in the neighbourhood and further. Because
178 of the cultural distance between asylum seekers and natives, natives may perceive more cultural
179 and safety threat as well. Previous research provided tentative support for a positive relationship
180 between the share of asylum seekers and perceptions of ethnic threat as well as negative stances
181 towards immigrants (Mayda, 2006; Hangartner *et al.* 2019; but see also Scheepers *et al.* 2002).
182 We thus expect that voters who have suddenly become exposed to asylum seekers in their
183 neighbourhood are more likely to support the PVV than their counterparts in neighbourhoods
184 who did not experience a sudden influx of asylum seekers (Hypothesis 1). And, on the basis of
185 conflict theory, that increased support for the PVV as a consequence of increased local exposure
186 to asylum seekers may be explained by increased perceptions of local intergroup threat
187 (Hypothesis 2).

188 Yet, the macro-structural theory of intergroup relations (Blau 1994) and contact theory
189 (Allport 1954) would suggest a different causal mechanism. Residential proximity to ASCs
190 may provide the opportunity to interact with asylum seekers (Blau 1994). Intergroup contact,
191 when positive, fosters tolerance (Allport 1954; Pettigrew and Tropp 2011). Hence, positive
192 contact with asylum seekers may make voters less inclined to support the radical right. The
193 influence of positive contact experiences can be explained by induced levels of knowledge,
194 empathy and perspective taking (Brown and Hewstone 2005; Pettigrew and Tropp 2011).
195 According to Allport, superficial contact (i.e. mere exposure) or overt negative contact, like
196 abuse and name-calling would only lead to more trouble (Allport 1954: 263). Intergroup contact
197 would only foster tolerance if contact takes place under ‘optimal’ conditions, like equal group

status or common objectives. However, Pettigrew and Tropp (2011) convincingly demonstrated in their meta-study that although the effect of intergroup contact is stronger if contact takes place under optimal conditions, commonly, these conditions are not necessary; intergroup contact – at least when not clearly negative – induces tolerance even if Allport’s conditions are not met (but see also Paluck *et al.* 2019 who point at a lack of experimental evidence for this claim).

Based on a choice experiment on preferences for refugee and migrant homes, Liebe *et al.* (2018) conclude that contact with refugees increases acceptance to refugee homes in the immediate vicinity, in line with contact theory. Studies that focused on the impact of intergroup contact on radical right voting seem to provide support for both the positive contact mechanism (Green *et al.* 2015; Rydgren, 2008; Savelkoul *et al.* 2017; but see also Savelkoul and Scheepers 2017) and the negative contact mechanism (Nijs *et al.* 2019). However, the presence of asylum seekers in ASCs may not always provide the most favourable opportunities for sustained positive interactions (cf. Dinas *et al.* 2019). It is thus not self-evidently true that increased proximity to asylum seekers leads to more positive contact experiences (cf. Enos 2014), or that it not at the same time leads to more negative contact experiences. That being said, we expect, on the basis of contact theory, that the presumed positive relation between increased local exposure to asylum seekers and increased support for the PVV as a result of feelings of ethnic threat may be suppressed by increased local positive interethnic contact experiences (Hypothesis 3).

Data and operationalization

1Vandaag Opinion Panel

This study employs individual-level panel data from the 1Vandaag Opinion Panel (1VOP) in the Netherlands. The 1Vandaag Opinion Panel consists of 50,000 people from all parts of the Dutch population living across the country. People sign up for this online panel of their own. Every week panel members give their opinion on current topics such as politics, economics, health care and crime. The results are announced in the broadcasts of ‘EenVandaag’ on public television and presented to politicians and policymakers. The advisory board of the 1VOP consists of Dutch University professors Joop van Holsteijn, Jelke Bethlehem and Tom van der Meer. More information on the panel can be found here (in Dutch): <https://eenvandaag.avrotros.nl/panels/opiniepanel/uitleg/>. For access to the original (anonymized) data we received from 1VOP, scholars may contact the owners of the 1VOP. For the current study we did not access any personal identifying data. Our study does not pose any

risk to panel members or their individual privacy and hence we did not deem it necessary to seek approval of Radboud University's Ethics Committee.

The measures used in this contribution are included in two waves of the 1VOP. Because people sign up for this online panel of their own, there is a self-selection bias in the sample of respondents (Bethlehem 2010). However, due to a uniquely large sample size we cover a high degree of the variety of people found within the Dutch population even though some groups (e.g. women, the young, lower educated) are underrepresented in the sample. The first wave of our data was collected in February 2015 and the second wave of our data was collected in November 2015. The period in between the two waves spanned the period in which the high influx of asylum seekers and the subsequent settlement of asylum seekers in residential environments throughout the Netherlands took place (Figure 1). As the focus of our study is on native Dutch individuals, we excluded respondents with a non-native Dutch background from our analyses (N=1,151). We classified respondents as native Dutch when both parents were Dutch, or when respondents identified as being Dutch in case one parent was non-Dutch.

1VOP panel members regularly receive invitations to fill in online questionnaires and can decide whether or not to participate in specific waves. Of the 26,064 native Dutch respondents who filled out the questionnaire in wave 1, 19,988 respondents also completed the questionnaire in wave 2. There was no significant relationship between becoming exposed to asylum seekers in the local environment, the main focus of our analysis, and the likelihood of participating in wave 2. PVV supporters of wave 1 had a .79 probability to participate in wave 2, non-PVV supporters a .76 probability. This selectively will lead to conservative tests of our hypotheses; we will be less likely to pick up an increase in PVV support over time in our panel data (see Table A1, Appendix).

The neighbourhood identifier included in the 1VOP is the four-digit part of the post code. The median number of residents in these neighbourhoods is 2,645 (mean=4,142) and the median surface area 5.35km² (mean=8.65km²).

Central Agency for the Reception of Asylum Seekers

We enriched our individual-level data with information from the Central Agency for the Reception of Asylum Seekers (COA) about the number of asylum seekers at the neighbourhood-level. COA is responsible for housing asylum seekers from the time they request asylum until they receive a residence permit or must leave the Netherlands. Due to the exceptionally high influx of asylum seekers in 2015, the maximum capacity of existing regular reception centres ('reguliere opvang') was soon reached. COA therefore opened new regular

reception centres but also housed asylum seekers in temporary centres ('noodopvang') and, starting from September 2015, also in crisis centres ('crisisnoodopvang'). Regular reception centres are used for at least a period of two years and have a capacity ranging from 300 to more than 1,500 people. Temporary centres were set up in, for example, remodelled market halls or empty office buildings. These centres generally house around 300 asylum seekers and are used for a period of six to twelve months. Various facilities were used as crisis centres, such as sport halls and old school buildings, which were already marked out by local governments to house citizens in times of incidents or disasters. Crisis centres give room to a dozen to several hundred asylum seekers, but only for short periods (in principle up to 72 hours) at a time. Before asylum seekers could be housed in crisis centres by COA, the local government needed – in principle – to agree. However, the placement process was chaotic and even for policymakers the procedures and responsibilities were unclear (Ministry of Justice and Safety, 2015).

Asylum seekers did not have any say in where they were going to be housed and because we assess changes in voting intention in a relatively short period of time, native residents are very unlikely to have moved out of the neighbourhood as a consequence of the inflow of asylum seekers. Selective residential mobility plaguing neighbourhood effects research in general (Hedman and Van Ham 2012) is thus unlikely to influence this study's results.

Notwithstanding that protests of the local population were more intense in some places than in others and that some municipal governments displayed a higher willingness to host asylum seekers than others, the increased exposure to asylum seekers was to a large extent an exogenous process for the neighbourhood residents whose voting intention it could affect. Voters of neighbourhoods that would experience an inflow of asylum seekers did not differ with respect to radical right support from voters that would not experience an inflow of asylum seekers: pre-crisis support for the PVV for both the 'treated' and 'untreated' groups was approximately 17%.

<<<Figure 1>>>

Changes in support for the PVV

To examine changes in voting intention for the radical right in the Netherlands, we measured respondents' intended voting behaviour at two time points with the following question: 'Which party would you vote for if parliamentary elections were held today?'. The answer categories consisted of the eleven largest political parties represented in the Dutch parliament as well as the option 'another party'. In addition, respondents could also answer 'I don't know', 'blank

vote', 'I'm allowed to vote, but I wouldn't', 'I'm not allowed to vote', and 'no answer'. We removed from the analysis the respondents who answered 'I'm not allowed to vote' and 'no answer' in one or both waves (less than 2%). Respondents who answered 'I don't know', 'blank vote', 'I'm allowed to vote, but I wouldn't' could in one of the two waves be politically mobilized or demobilized and experience respectively a shift towards or a shift away from the radical right and are therefore included in our analysis. Voting intention for the PVV is included as dichotomized variable (YES=1 vs. NO=0).

Exposure to asylum seekers

For each ASC we know the exact address. Depending on the type of ASC we received different information from COA. For regular and temporary ASCs we know how many asylum seekers were housed at 1-1-2015 and 15-11-2015. For each crisis centres we know the daily mutations in asylum seekers from 18-9-2015 until 15-11-2015. Before 18 September, asylum seekers were not housed in crisis centres. The data of COA thus allowed us to capture the change in exposure that took place *after* respondents were interviewed for the first time and *before* respondents were interviewed for the second time. To account for differences in sizes between neighbourhoods, we calculate the number of asylum seekers per 1,000 inhabitants. We acknowledge that the exposure to asylum seekers and the impact of this exposure for voting intentions may depend on the type of ASC asylum seekers were housed in. Native residents living close by regular ASCs may already have been familiarized by the presence of asylum seekers (Lubbers *et al.* 2006). This may mitigate the impact of increased exposure on PVV support. Asylum seekers could only live very briefly in the same crisis ASCs (generally up to 72 hours), which will have made it difficult to develop sustained positive interactions with native neighbourhood residents. Especially among neighbourhood residents who have become exposed to asylum seekers as a consequence of placement of asylum seekers in crisis ASCs, we may therefore expect the threat mechanism to dominate. Thus, besides the measure of total relative exposure to asylum seekers, we also calculate the increase in the number of asylum seekers in regular ASCs, in temporary ASCs, and in crisis ASCs separately.

Ethnic threat and interethnic contact

Feelings of local interethnic threat are measured with the item: 'I sometimes worry about the fact that my neighbourhood deteriorates because of the arrival of ethnic minorities'. The answer categories are: 0. 'totally disagree', 1. 'disagree', 2. 'agree/nor disagree'/'I don't know/no opinion', 3. 'agree', and 4. 'totally agree'. We measure local positive interethnic contact with

non-western ethnic minorities with the following question: ‘How often do you have personal contact in your neighbourhood with people of non-western descent? By personal contact, we mean that you know the name of this person and occasionally have a conversation with this person.’. The answer categories to this item are: 0. ‘never’/‘not applicable’, 1. ‘about once a year’, 2. ‘several times a year’, 3. ‘about once a month’, 4. ‘several times a month’, 5. ‘several times a week’, and 6. ‘(almost) every day’.

Missing values and working sample

We removed 506 respondents (2.5%) for whom we could not match the contextual information about the exposure to asylum seekers in the local living environment due to missing information on their geographical location. This left us with a working sample of 19,091 respondents in 2,997 four-digit postcode areas (74% of all inhabited postcode areas). Descriptive statistics of our main variables – based on the final samples used in our analyses – are displayed in Table 1.

Analytical strategy

To test our hypotheses, we employ both fixed effects and hybrid models. In fixed effects models the influence of all time-invariant characteristics are removed, allowing us to assess the net effect of being exposed (more precisely: changes in exposure) to asylum seekers in the local living environment on individuals’ changes in voting intentions. The fixed effects analyses are based on a reduced sample of the respondents whose voting intentions changed over time (N=1,389, living in 1,002 neighbourhoods). Fixed effects models tell us what would happen to an individual’s voting intention if the exposure to asylum seekers would increase by one unit given that these individuals have changed their voting intention between time point 1 and time point 2. Because voting intentions for the PVV are operationalized as a dichotomous variable, we estimate logistic fixed effects models.

In our hybrid models (aka ‘between-within method’), time-varying predictors are decomposed into a between-person component (i.e. person-specific mean) and a within-person component (i.e. deviation from person-specific mean). Time (i.e. wave) is included as fixed-effect. The causal estimates tell us how experiencing a change (e.g. in exposure to asylum seekers) is related to a change in the odds to vote for the PVV. An advantage of this method is that respondents who did not experienced a change in voting intention can also be included. We included additional time-constant controls for neighbourhood ‘poverty’ (i.e. average house price) and ‘percentage of non-western minorities’. The latter naturally excludes asylum seekers. At the individual level, we controlled for the time-constant variables gender, age, and education.

Our hybrid analysis are based on the total sample of 19,091 respondents living in 2,997 different neighbourhoods.

We made a detailed replication package (website) for this paper (including datasets, scripts, additional tests; weblink: XXX). It not only allows the interested reader to replicate all our results and claims made in the paper but also to assess the impact of different operationalisations and modelling strategies.

<<<Table 1>>>

Results

Among voters who changed their support for the PVV, voters are far more likely to have voted for the PVV in wave 2 compared to wave 1: among the switchers, 75.88% voted for the PVV in wave 2 (Table 1). In general, support for the PVV increased as indicated by the percentages referring to the hybrid sample: from 16.72% in Wave 1 to 20.48% in Wave 2. Although on average the increase in feelings of threat and intergroup contact experiences are relatively small (0.16 and 0.26, respectively for the fixed effects sample), there is quite some within-individual variation in changes in feelings of threat and contact. As expected, we see that asylum seekers are housed in crisis centres only in wave 2. Among our respondents, approximately 8% experienced an inflow of asylum seekers in their neighbourhood. This illustrates that although the 2015 refugee crisis was the biggest refugee crisis the Netherlands experienced in recent history, only a relatively small percentage of voters became directly exposed to asylum seekers in their local neighbourhood environment.

<<<Table 2>>>

Table 2 displays the results based on the logistic fixed effects models. The positive coefficient for Wave 2 indicates that, irrespective of whether residents have witnessed an influx of asylum seekers in their neighbourhood, the odds of voting for the PVV have increased over time ($b=1.118$ $se=0.064$, Model 1, Table 2). On top of this general increase in support for the PVV, people who have suddenly become exposed to asylum seekers as a result of the establishment of an ASC in their neighbourhood are even more likely to switch to the PVV than to switch away from the PVV ($b=0.022$, $se=0.012$; Model 1, Table 2). This corroborates hypothesis 1. With each unit increase in the exposure to asylum seekers – an increase of one asylum seeker per 1,000 inhabitants – ceteris paribus, the odds for an individual to vote for the PVV increase by 2.2% ($\exp(0.022)$). In Model 2 we break down exposure to asylum seekers by type of ASC.

All estimates referring to exposure are positive but only an increase of exposure to asylum seekers housed in crisis centres is significantly related ($p < 0.10$, two-tailed) to people's likelihood to vote for the PVV ($b = 0.028$, $se = 0.017$; Model 2, Table 2). That said, the coefficients of all three types of ASCs do not significantly differ from one another: LR $\chi^2(2) = 1.31$.

With Model 3, we test the threat mechanism. In line with conflict theory, we find that people who experienced an increase in feelings of ethnic threat are more likely to have switched to the PVV ($b = 0.268$, $se = 0.058$; Model 3, Table 2). With one unit increase in ethnic threat, the odds for a single individual to vote for the PVV increase by 31% ($\exp(0.268)$). Increased positive contact with non-western minorities is not significantly related to PVV-voting (Model 4, Table 2) and thus also does not suppress the threat mechanism. Including ethnic threat and contact into our explanatory model simultaneously does not substantially alter the estimates of exposure to asylum seekers (estimates referring to exposure are almost identical across Model 2 and Model 5). Neither increased threat nor contact is more common among residents who experienced increased exposure to asylum seekers than among residents who did not experience an increase in exposure to asylum seekers. There was a significant difference in changes in contact for voters who did not experience an inflow of asylum seekers ($M = 0.296$, $SD = 2.164$) and voters who did ($M = -0.198$, $SD = 2.190$); $t(129.37) = 2.285$, $p = 0.024$ but in the opposite direction as expected. There was no significant difference in changes in threat for voters who did not experience an inflow of asylum seekers ($M = 0.170$, $SD = 1.113$) and voters who did ($M = 0.108$, $SD = 1.170$); $t(127.89) = 0.534$, $p = 0.594$. T-tests performed on fixed-effects sample. Thus, notwithstanding that heightened perceptions of ethnic threat are an important explanatory factor for changes in PVV support, we therefore refute both hypotheses 2 and 3.

The results of our hybrid models are summarized in Table 3. Results referring to the main variables of interest – exposure to asylum seekers – led to identical conclusions as described above, even though the estimates are smaller than the estimates produced by the fixed effects models, as expected (Allison 2009). A change in total exposure to asylum seekers is significantly ($p < 0.10$, two-tailed) related to the odds to vote for the PVV: with each unit increase in the total exposure to asylum seekers the odds to vote for the PVV increases slightly by 0.1% (Model 1). Holding all covariates at their mean, for female voters who did not experience an inflow of asylum seekers the probability to vote for the PVV after the crisis was 13.4%, for female voters who experienced an inflow of 100 asylum seekers per 1,000 neighbourhood residents the probability was 15.1%. For their male counterparts the estimated probabilities are 21.6% and 24.1%, respectively (predicted probabilities based on estimates as

summarized in Table 3, Model 1). The impact of increased exposure (change in probabilities of 1.7% for women and 2.5% for men) is substantial in comparison to the general trend in increased support for ‘non-treated’ voters; increased probabilities of 2.7% for women and 4.0% for men.

The estimates referring to exposure to asylum seekers housed in specific types of ASCs are positive but no longer reach significance (Model 2). When voters’ feelings of threat increased ($b=0.117$, $se=0.020$, Model 3) and, surprisingly, when positive contact with non-western immigrants increased ($b=0.018$, $se=0.007$, Model 4), their support for PVV increased as well. As can be seen in Model 5, taking into account whether or not people experienced an increase in contact with non-western immigrants did not affect the threat mechanism. Thus our hybrid models also confirm hypothesis 1 and refute hypotheses 2 and 3.

The estimates referring to the time-constant (between) predictors are in line with previous research (cf. Savelkoul et al. 2017). Most importantly, voters with higher mean levels of threat are more likely to vote for the PVV ($b=1.414$, $se=0.023$, Model 3). Voters who have more positive contact with non-western immigrants in their neighbourhood are less likely to vote for the PVV ($b=-0.058$, $se=0.010$, Model 4). The (between-level) estimates referring to exposure to asylum seekers are not significant. This illustrates that the placement of ASCs has been exogenous to people’s (pre-crisis) party preference.

<<<Table 3>>>

Robustness checks

If people’s voting intentions change, they mainly change within the left-wing bloc consisting of Labour (PvdA), GreenLeft (GL) and the Socialist Party (SP) or within the right-wing bloc consisting of liberal-conservatives (VVD), Christian-democrats (CDA) and the PVV (Van der Meer *et al.* 2015). An exception is the exchange between the PVV and the SP, which are both considered to be populist, anti-establishment parties (Bakker *et al.* 2015; Immerzeel *et al.* 2016).

It could be that the PVV lost votes to other parties of the right-wing bloc and won votes from the anti-establishment party SP (or vice-versa), thereby obscuring the general trend of increasing PVV popularity. Moreover, volatility patterns could differ between people who did and did not become exposed to asylum seekers in their neighbourhood in 2015. This may explain in part our small and/or non-significant estimates for our exposure measures reported above. As a robustness check, we therefore also ran multinomial fixed effects models (Table A2, Appendix; voting intention for the PVV is now the base category). It turns out that during

the refugee crisis, the PVV was especially successful in attracting voters from the other anti-establishment party (i.e. SP), as indicated by the estimate of ‘wave 2’ referring to the odds ‘Anti-establishment vs. PVV’ ($b=-2.008$, $se=0.105$; this estimate differs significantly from the estimate of ‘wave 2’ referring to the odds ‘Other Parties vs. PVV’: $LR\ chi^2(1)=294.87$). Of our exposure measures, only ‘exposure to asylum seekers in crisis centres’ reaches significance and only for the odds ‘Right wing vs. PVV’ and ‘Other parties vs. PVV’. However, all estimates referring to ‘exposure to asylum seekers in crisis centres’ are negative and do not significantly differ from one another. The impact of exposure to asylum seekers does not depend on pre-crisis voting intentions (cf. Karreth *et al.* 2015).

Several scholars have suggested that the impact of increasing diversity on related concepts such as prejudice may depend on, for example, residents authoritarian values (Velez and Lavine, 2017), national rhetoric (Hopkins, 2010), or the initial share of outgroups (Newman, 2013). Because this contribution is interested in the average impact of increased exposure to asylum seekers, because even with our impressive dataset, still relatively few neighbourhoods faced an inflow of asylum seekers, and because our survey lacked measures of most likely potential moderators, we did not formulate hypotheses on the conditional impact of exposure to asylum seekers. That said, in additional analyses using our hybrid models, we tested for an interaction between initial levels of ethnic density (i.e. percentage of non-western minorities) and increases in exposure to asylum seekers but these did not reach significance (see replication package).

In line with most previous research on the impact of the ethnic composition of the neighbourhood and support for the radical right, we operationalized exposure to asylum seekers as relative group size, in this case, the number of asylum seekers per 1,000 neighbourhood residents. For crisis centres, our exposure measure refers to the average number of asylum seekers for the days that the centre housed asylum seekers. To try to capture the time heterogeneity in exposure to asylum seekers housed in crisis centres, we multiplied the number of days asylum seekers were housed in each crisis centre (range: 1 - 41) with the number of asylum seekers at that specific day (range: 20 – 420). To take into account differences in neighbourhood size, this score was divided by the number of neighbourhood residents (per 1,000). The Spearman’s ρ statistic between the original exposure measure and this alternative operationalization was .53. The alternative operationalization of exposure to asylum seekers in crisis centres did not reach significance in our additional analyses (Table A3, Appendix). This may indicate that exposure to more asylum seekers is more likely to fuel support for the radical right but that longer exposure to asylum seekers may dampen this effect, possibly due to a

familiarization process (cf. Lubbers *et al.* 2006). In line with this idea, we observe that the estimated impact of the number of days asylum seekers were housed in crisis centres on PVV support was negative ($b=-0.113$; $se=0.043$), and, once we control for differences in time use between crisis centres, our original exposure measure becomes stronger ($b=0.64$; $se=0.025$; Table A3, Appendix). Binary exposure measures (yes/no increase in asylum seekers) did not reach significance (Table A3, Appendix). This operationalization of exposure may simply be too blunt and our non-significant findings may indicate that it is not so much whether asylum seekers were housed in one's neighbourhood but about how many asylum seekers entered the neighbourhood.

As stated above, because people sign up for the 1VOP online panel of their own, there is a self-selection bias in the sample of our respondents. As a robustness check we repeated our fixed effects analysis on a weighted sample (based on sex, age and educational level). For this weighted sample, we find that both exposure to asylum seekers in temporary ASCs and crisis ASCs is related to an increase in support for the PVV (Table A3 and A4, Appendix).

We argued above that our study comes close to a natural experiment; voters who experienced an inflow of asylum seekers (the treatment) were similar to voters who did not experience an inflow of asylum seekers. With our individual-level panel data we were already able to take unobserved time-stable heterogeneity into account. With a natural experiment, unobserved time-varying heterogeneity (including pre-treatment trends in PVV support) is not likely to have biased our results. However, we acknowledge that group differences may have occurred by chance and that the distribution of asylum seekers may not have been perfectly random. As a robustness test, we therefore used a nonparametric pre-processing matching approach on the sample which we used to estimate our fixed effects models. We used a binary treatment variable (increase in exposure = 1) in the matching procedure. The pre-treatment covariates on which we perform a nearest neighbours match are: age, gender, education, threat, contact, ethnic density in neighbourhood and socio-economic status of the neighbourhood. Matching our data leads to a somewhat stronger estimated impact of exposure to asylum seekers in crisis ASCs (Table A3 and A5, Appendix).

Following the suggestion of an anonymous reviewer, we also estimated a Difference in Differences estimator. The traditional DiD model for individual-level panel data with additional time-constant covariates c_i is:

$$Y_{it} = \beta_1 Time_t + \beta_2 Treat_i + \delta(Time_t \cdot Treat_i) + c_i + \epsilon_{it} , \quad (1)$$

with δ being the DiD estimator and $Treat_i$ the dichotomous treatment variable and Y_{it} the continuous outcome variable. Formula (1) is equivalent to:

$$\Delta Y_i = \beta_1 + \delta Treat_i + \epsilon_i \quad (2)$$

Since our outcome is a binary variable there is no standard DiD model. Our main results reported in Table 2 are therefore based on the following model:

$$\text{logit}(\Pr(\Delta Y_i = 1 | Treat_i)) = \beta_1 + \delta Treat_i, \quad (3)$$

with $\Delta Y_i = 1$ if the dependent outcome was 1 post-treatment (i.e. wave 2) and 0 if the dependent variable was 1 pre-treatment (wave 1). Our $Treat_i$ variable is the change in exposure the asylum seekers. Formula (3) is the fixed effects logistic regression model for two waves (or, more precisely, the first difference model which for two waves is equivalent to the more general fixed effects model). Note, that respondents who did not change support for the PVV drop out of this analysis. Because we have a binary outcome and we use a nonlinear link function we cannot interpret δ as the DiD estimator. Moreover, our original ‘treatment’ variable is not a dichotomous variable, and this also makes why we cannot interpret our effect as the traditional DiD estimator. To be able to interpret our effect as a DiD estimator, we estimated formula (1) directly for a binary outcome variable as an additional robustness check (on our complete sample of panel respondents). That is, we estimated a linear probability model (LPM), while controlling for heteroscedasticity in the error term. We did this once with our original continuous ‘treatment’ variable and once applying a dichotomization. To avoid any possible post-treatment bias we did not include our time-varying contact or threat measures. We estimated models with and without time-stable covariates. We summarized the DiD estimators in Table A6 (Appendix). The DiD estimators based on binary treatment variables do not reach significance. Above we already observed that it is not whether the neighbourhood experienced an inflow of asylum seekers but how many asylum seekers entered the neighbourhood (Table A3, Appendix). The DiD estimators based on continuous treatment variables reached significance (albeit only in models without additional covariates) in line with our results reported in Table 2 and Table 3.

Conclusion and discussion

In 2015 an unprecedented number of asylum seekers had to be housed in existing and haphazardly created new (temporary and crisis) asylum seekers centres. Our large-scale

individual-level panel data on voting intentions provided us with an unique opportunity to expand academic knowledge about the relationship between the influx of asylum seekers in the local environment and support for the radical right. During the refugee crisis support for the radical right increased and especially among people who experienced an increase in exposure to asylum seekers in their neighbourhood. In the Netherlands, people appear to be receptive of abrupt, rapid and visible increases in the number of immigrants, which might coincide with a ‘not-in-my-back-yard’ syndrome (Ferwerda *et al.* 2017). Based on several robustness analyses, we tentatively conclude that larger inflows of asylum seekers in the neighbourhood (relative to the group size of native residents) fuel support for the PVV, at least in the short run. When asylum seekers stay in the neighbourhood for longer, this impact may be curbed (Lubbers *et al.* 2006). We encourage scholars to replicate our findings, preferably in different countries.

We tested our hypotheses employing individual-level panel data allowing us to control for (time-stable) unobserved heterogeneity. Given the short time-window between our survey waves, selective residential mobility did not plague our study. Moreover, exposure to asylum seekers was to a large extent random and our study therefore resembled to some extent a natural experiment. Because of these three reasons, combined with the fairly consistent results over different modelling strategies, many data and model requirements are met to give a causal interpretation to our finding that an inflow of asylum seekers into the neighbourhood is related to an increase in radical right support in this neighbourhood. However, we need to acknowledge that a natural experiment is not a true experiment and that our estimates only reached the boundary of the conventional significance criteria.

War refugees are considered to be more deserving to enter and stay in the Netherlands (cf. Bansak *et al.* 2016) than ‘classical migrants’. Consequently, the impact of similar unexpected sharp increases in the size of migrant populations in neighbourhoods that result from union formation and labour migration on radical right voting may be larger. Naturally, these latter migration flows are generally less volatile than migration flows as a result of a humanitarian crisis and this may explain why previous research only observed small effects of changing migrant sizes in neighbourhoods on radical right voting (e.g. Savelkoul *et al.* 2017).

This study is one of the first to demonstrate the previously established threat-radical right relationship (e.g. Lucassen and Lubbers 2012; Werts *et al.* 2012) from a longitudinal perspective; residents whose worries about neighbourhood deterioration resulting from migration increased during the refugee crisis were more likely to start expressing intentions to vote for the PVV. Even though our results thus confirmed that increasing feelings of local ethnic threat are an important driving force for support for the radical right, this could not explain why

especially residents of neighbourhoods in which asylum seekers were housed became more likely to vote for the PVV. This is because an inflow of asylum seekers did not increase feelings of neighbourhood deterioration. We need to acknowledge that our single-item threat measure did not explicitly refer to economic, cultural or safety issues in the neighbourhood because of the inflow of asylum seekers. With a better (multi-item) measurement instrument we may have picked up the assumed relation between the inflow of asylum seekers and increased feelings of ethnic threat. However, our null finding, is in line with previous studies, using different measures of ethnic threat.

It could be the case that not necessarily anti-immigrant attitudes increased as a result of the influx of asylum seekers but that already previously held (negative) opinions regarding immigration became more salient in these neighbourhoods. This resonates with the idea of Karreth *et al.* (2015) that increasing diversity is only related with negative attitudes towards immigrants among people on the political right. At the national level, the share of the Dutch population that mentioned immigration as one of the two most important issues facing the Netherlands at the moment increased between February 2015 and November 2015 from 9% to 56% (European Commission, 2015a; 2015b; own calculations). Heightened issue salience is likely to increase the relative importance that voters attach to this issue. A promising direction for future research would therefore be to assess the role of (increased) issue saliency in the link between (increased) local outgroup size and support for the radical right.

We expected that increased positive contact with minorities would mitigate the impact of increased exposure to asylum seekers on radical right voting. In line with contact theory, we observed that voters who have more contact with non-western minorities are less likely to vote for the radical right as compared to voters with less contact with non-western minorities. Unexpectedly, at the same time we observed that residents who experienced an *increase* in positive interethnic contact during the refugee crisis became more likely to express support for the radical right; the estimates referring to the between and within effects of interethnic contact were opposite in direction. Increased positive interethnic contact did not suppress the threat mechanism. As contact opportunities may lead to both positive and negative contact, it may be that the same voters who experienced an increase in positive contact also experienced an increase in negative contact and that the impact of negative contact experiences on voting intentions was more severe. A recent study showed that negative contact experiences predict support for the PVV, even after controlling for indicators of threat (Nijs *et al.* 2019).

Political parties had to come clean during the refugee crisis as to their position on the immigration issue in general and as to their position on whether and where to house asylum

636 seekers in particular. The VVD (next to the PVV the main anti-immigration party) definitely
637 showed colours by making it perfectly clear that to limit the influx of even more asylum seekers
638 it was willing to endorse the EU-Turkey agreement (i.e. the ‘refugee deal’). This may explain
639 why the PVV was not especially successful in attracting new voters from the VVD during the
640 refugee crisis. Instead, we demonstrated that especially former voters for the Social Party (SP)
641 were likely to switch to the PVV. Volatility patterns are thus clearly context dependent. The SP
642 shares the radical right’s anti-establishment rhetoric, but as owner of the issue of immigration
643 (Kleinnijenhuis and Walter 2014) the radical right used its anti-establishment rhetoric to
644 successfully capitalize on the convergence of the immigration and anti-establishment issue
645 during the 2015 refugee crisis at the expense of the Socialist Party.

646 The radical right gained support in the Netherlands during the 2015 refugee crisis and
647 especially among residents who were exposed to asylum seekers ‘in their backyard’. Why this
648 is so remains unclear; the threat mechanism does not seem to hold. We encourage scholars to
649 test two alternative ideas we could unfortunately not test ourselves: the negative contact
650 mechanism and the issue salience argument.

Notes

a: 116 respondents living in 81 different neighbourhoods experienced a change in the number of asylum seekers.

b: 1,491 respondents living in 175 different neighbourhoods experienced a change in the number of asylum seekers.

c: In Wave 2 1.75% switched from the PVV to another voting option; 5.51% switched to the PVV from another voting option.

+ $p < 0.10$; * $p < 0.05$; (two-tailed test).

Notes: Right wing: VVD, CDA and SGP; Anti-establishment: SP; Other parties: PVDA, D66, CU, GL, PvdD, 50PLUS and 'another party'; Demobilized 'I don't know', 'blank vote' and 'I'm allowed to vote, but I wouldn't'. To create this categorization, we used information from the 2014 Chapel Hill Expert Survey on party position on immigration policy as well as the salience of anti-establishment and anti-elite rhetoric (Bakker et al., 2015).

Exposure to Asylum Seekers and Changing Support for the Radical Right: A Natural Experiment in the Netherlands

As a result of the 2015 refugee crisis, a substantial number of voters experienced a sudden and unexpected influx of asylum seekers in their neighbourhood in the Netherlands. We examined whether and why local exposure to asylum seekers leads to more support for the radical right (i.e. PVV). Our analyses are based on a longitudinal individual-level panel dataset including more than 19,000 respondents (IVOP) who were interviewed just before and shortly after the height of the refugee crisis.

We enriched this dataset with detailed information about where ~~refugees~~ asylum seekers were housed from the Central Agency for the Reception of Asylum Seekers. Our empirical study resembles a natural experiment, because some residents experienced an increase in exposure to asylum seekers but similar residents did not. ~~We find that~~ PVV support increased during the refugee crisis and especially among residents who became more exposed to asylum seekers in their neighbourhood. ~~PVV support increased.~~

Keywords: populist radical right; asylum seekers; natural experiment; ethnic threat; interethnic contact

Introduction

An unprecedented refugee crisis unfolded in Europe over the course of 2015, which brought about political turmoil in many countries. In this study we take a closer look at changes in support for the radical right in the Netherlands against the background of a large influx of asylum seekers in that year. As some people witnessed an influx of asylum seekers in their residential neighbourhood, while others did not, the 2015 European refugee crisis is an interesting case to study the impact of local demographic changes on voting intentions for the radical right.

In 2015, the twenty-eight member states of the European Union together with Norway and Switzerland received more than 1.3 million applications from asylum seekers (Eurostat, 2016). This has been, by far, the highest annual number of asylum seekers recorded in Europe since World War II (OECD 2015). The majority of the asylum seekers that arrived in Europe in 2015 came from Muslim-majority countries. In the Netherlands – the current site of study – more than 40,000 asylum seekers (255 applicants per 100,000 inhabitants) entered the country in 2015, a historical record. The centre-left (PvdA) and centre-right party (VVD) forming the Dutch government fiercely debated the development of a strategy for dealing with these asylum seekers. The refugee crisis not only evoked divergent reactions among Dutch politicians but also among the broader public. The Dutch people made their voice heard, both in support of and in opposition to the arrival of asylum seekers. While the Netherlands Red Cross saw their stock of temporary volunteers grow from 6,000 to more than 36,000 (The Netherlands Red Cross 2015), public demonstrations against the arrival of asylum seekers also intensified over the course of 2015. Especially in communities where new asylum seeker centres (ASCs) were established, people uttered their disapproval by, for example, hanging banners on the assigned buildings with anti-refugee slogans, such as ‘Own people first’.

In this study, we take advantage of a large-scale longitudinal individual-level panel dataset to examine changes in support for the radical right against the background of the sudden arrival of asylum seekers in the Netherlands. In particular, we are interested in whether voters ~~changechanged~~ their intentions to vote for the radical right ~~as a result of~~ ~~after~~ having experienced an ~~influx~~ ~~inflow~~ of asylum seekers in their residential neighbourhood.

The *Partij voor de Vrijheid* (Party for Freedom; PVV) was in 2015 the only radical right party in the Netherlands with seats in Parliament (Bakker *et al.* 2015; Immerzeel *et al.* 2011). The PVV was founded in 2006 and since then led by Geert Wilders. The PVV is known for its anti-immigration statements and its campaign to ‘de-Islamize’ the country. During the refugee crisis, the PVV started targeting (Muslim) asylum seekers in its political discourse. Wilders

announced in October 2015 the launch of a website where people can report complaints about asylum seekers (PVV, 2015). During new year's eve 2015, mass sexual assaults took place in Cologne, Germany. Relatively many of the identified suspects were asylum seekers (Connolly 2016). Wilders subsequently propagated that all male asylum seekers should be locked up (Sims 2016). The PVV is, therefore, an attractive party for voters with (strong) anti-migration, anti-Muslim and anti-asylum seeker attitudes.

The ethnic composition of people's living environment is a focal point in scholarly attempts to explain the popularity of radical right parties (e.g. Coffé *et al.* 2007; Edo *et al.* 2019; Green *et al.* 2015; Lubbers and Scheepers 2002). In the Netherlands, support for the radical right among native-Dutch is more common in neighbourhoods where more non-western migrants (and their descendants) live (e.g., Janssen *et al.*, 2019; Savelkoul *et al.* 2017). Yet, war refugees are clearly a distinct group compared to immigrants who enter destination countries such as the Netherlands as a result of union formation, family reunification and labour migration. It is likely that, in general, war refugees are considered to be more deserving to enter and stay in receiving countries (cf. Bansak *et al.* 2016) and that they may therefore provoke less opposition.

Having said that, previous research has shown that a larger influx of asylum seekers is positively related with more support for the radical right (e.g. Arzheimer 2009; Kessler and Freeman 2005; but see also Arzheimer and Carter, 2006). However, studies addressing this relationship are largely restricted to the country-level and generally draw on cross-sectional data collected before the 2015 European refugee crisis. Research addressing the influx of asylum seekers in local residential areas and its consequences for people's voting intentions is scarce. Dustmann, Vasiljeva and Damm (2019) showed that the allocation of larger refugee shares in Danish municipalities in the 1980's and 1990's was related with higher vote shares for anti-immigration parties. Dinas and colleagues (2019) demonstrated that the massive but transient inflow of refugees on Aegean islands during the 2015 European refugee crisis fuelled support for the extreme-right on these islands. Besides focusing on relatively large geographical units, both studies employed a macro-level approach – i.e., focusing on vote shares, rather than individual voting intentions and changes thereof over time – which does not allow to empirically assess underlying mechanisms for this relationship.

In this study, we aim to contribute to earlier research in two ways. Taking advantage of individual-level longitudinal panel data, we will first examine whether Dutch voters who have been exposed to a sudden and unexpected influx of asylum seekers in their local neighbourhood are more (or less) likely to *change* their voting intention to the PVV than voters who have not

Formatted: Font: Italic

96 been exposed to an inflow of asylum seekers in their neighbourhood. Second, we aim to explain
97 any observed relationship between the influx of asylum seekers in the neighbourhood and
98 support for the radical right.

99 A positive relationship between the two phenomena may be explained by the threat
100 mechanism (e.g. Blalock 1967; Coser 1956; Quillian 1995) stating that an increasing ethnic
101 outgroup size fosters feelings of economic and cultural ethnic group threat, and consequently,
102 anti-immigration attitudes which are the central attitudinal driving force behind support for the
103 radical right (e.g. Ivarsflaten 2008; Rydgren 2007). -At the same time, residential proximity to
104 ASCs may lead to contact with asylum seekers (Blau 1994). Positive intergroup contact
105 stimulates interethnic tolerance (Allport 1954; Pettigrew and Tropp 2011), which can be linked
106 to lower levels of support for the radical right. ~~Increased positive contact may thus suppress a~~
107 ~~positive relationship between an influx of asylum seekers in the neighboured and increased~~
108 ~~support for the radical right.~~ The few, cross-sectional studies putting both mechanisms to the
109 test, found support for both the threat and the positive contact mechanism, albeit weaker for the
110 latter (Green *et al.* 2015; Rydgren 2008; Savelkoul *et al.* 2017). We are the first to test both the
111 threat and ~~(positive)~~ contact mechanisms simultaneously from a longitudinal perspective, using
112 individual-level panel data in the context of the refugee crisis.

113 To reach these aims, we employ a longitudinal and sizeable panel dataset on individual
114 respondents (N>19,000; 1Vandaag Opinion Panel Survey). Our panel dataset allows us to
115 control for (time-stable) unobserved heterogeneity. We enriched this micro-level data with
116 detailed information about where ~~refugees~~asylum seekers were housed from the Central
117 Agency for the Reception of Asylum Seekers (COA). Formally, the term ‘asylum seeker’ refers
118 to persons who apply for asylum and seek refugee status. We therefore use this term when we
119 talk about the persons who were housed in the ASCs during the 2015 refugee crisis. We use the
120 term ‘refugee’ more loosely to refer to persons fleeing the risk of serious harm and persecution
121 (and who may or may not have an official refugee status).

122 The period in between the two waves of our data (February and November 2015)
123 spanned the period in which the settlement of asylum seekers in residential environments
124 throughout the Netherlands took place. Asylum seekers were unable to select the region where
125 they wanted to be housed. Similarly, neighbourhood residents had no, or only limited influence,
126 in where new asylum seekers were going to be housed and, within the time-window of our
127 study, did not have time to move out of their neighbourhood if they opposed to the ~~influx~~inflow
128 of ~~refugees~~asylum seekers. Selective residential mobility, generally plaguing the
129 neighbourhood effects literature, is thus not an issue. Given the sudden and unexpected influx

Formatted: Indent: First line: 0.49"

of ~~refugees~~asylum seekers, the management of ~~refugees~~asylum seekers flows was chaotic and haphazard. The placement of asylum seekers was – as we will show below – to a large extent random and therefore our study resembles to some extent a natural experiment. For these three reasons – individual-level panel data allowing to control for (time-stable) unobserved heterogeneity, no selective residential mobility, increased exposure to asylum seekers (to a large extent) random – we are thus able to make relatively strong causal claims on the impact of the refugee crisis on changing support for the PVV.

Theoretical expectations

According to conflict theories (Blalock 1967; Coser 1956, Quillian 1995), a larger relative size of non-natives in people's living environment induces competition between natives and non-natives for scarce economic resources (e.g. jobs and affordable housing). Conflicting cultural values (e.g. toward homosexuals or freedom of speech), also, become more apparent when the group of non-natives is more sizeable. After reviewing approximately 100 studies of immigration attitudes, Hainmueller and Hopkins (2014) conclude that perceptions of group threat affect immigration attitudes. This holds especially for concerns about the cultural impact of immigration, and not so much the possible consequences of immigration for one's personal (economic) situation. Because earlier research convincingly showed that voters who perceive ethnic minorities as a threat and who hold anti-immigration attitudes are more likely to cast their vote for the radical right (e.g. Green *et al.* 2015; Lucassen and Lubbers 2012; Werts *et al.* 2012), one would also expect to observe a positive relationship between the presence of non-natives in people's living environment and their likelihood to vote for the radical right.

~~Yet, previous~~Previous empirical studies reached mixed conclusions when it comes to the relationship between the ethnic composition of people's *local* living environment and their likelihood to vote for the radical right. Whereas several studies provided support for a positive relationship (e.g., Coffé *et al.* 2007; Lubbers and Scheepers 2002; Valdez 2014), others found no significant relationship (Lubbers and Scheepers, 2000) or even a negative relationship (Bowyer 2008; Rydgren and Ruth 2013). For the Netherlands, previous studies showed that support for the radical right is more common in neighbourhoods with a larger share of non-western migrants (Janssen *et al.* 2019; Savelkoul *et al.* 2017; but see also Van Wijk *et al.*, 2020 who found a U-shaped relationship). These studies lack, however, convincing evidence for a threat mechanism. This was due to the fact that outgroup sizes at the neighbourhood level were not consistently linked to more intense feelings of ethnic group threat, a null-finding reported

by others as well (e.g. Pettigrew *et al.* 2010; Pottie-Sherman and Wilkes 2017; Schlueter and Wagner 2008).

Olzak (1992) was one of the first scholars who argued that recent substantial increases rather than stable levels of non-natives in people's living environment trigger perceptions of ethnic threat. In line with this idea, several studies provided empirical evidence for a positive relationship between an increase in immigrants and voting for the radical right (e.g., Kessler and Freeman 2005; Lubbers and Scheepers 2000; but see also Lubbers *et al.* 2000). The 2015 European refugee crisis provides an interesting case to test the impact of a sudden demographic change on radical right voting. At the country-level, several studies provided support for a positive relationship between the share as well as the influx of asylum seekers and support for the radical right (e.g. Arzheimer, 2009; Kessler and Freeman 2005; but see also Arzheimer and Carter, 2006). Similar relationships have been found at somewhat lower geographic scales (Dinas *et al.* 2019; Dustmann *et al.* 2019).

Although asylum seekers in the Netherlands do not directly compete with natives for jobs – they are not allowed to work – they do receive a small allowance and, once they are granted a refugee and permanent resident status, will compete for public housing. This is likely to trigger perceptions of economic threat among natives. Refugees/Asylum seekers in the Netherlands are not confined to ASCs and are allowed to wander free in the neighbourhood and further. Because of the cultural distance between refugees/asylum seekers and natives, natives may perceive more cultural and safety threat as well. Previous research provided tentative support for a positive relationship between the share of asylum seekers and perceptions of ethnic threat as well as negative stances towards immigrants (Mayda, 2006; Hangartner *et al.* 2019; but see also Scheepers *et al.* 2002). We thus expect that sudden increases of voters who have suddenly become exposed to asylum seekers in people's their neighbourhood will be consistently related are more likely to support for the radical right, as unexpected noticeable changes the PVV than their counterparts in neighbourhoods who did not experience a sudden influx of asylum seekers (Hypothesis 1). And, on the presence basis of non-natives in people's living environment will trigger feelings conflict theory, that increased support for the PVV as a consequence of increased local exposure to asylum seekers may be explained by increased perceptions of local intergroup threat, driving them to vote for the radical right. (Hypothesis 2).

Yet, based on the macro-structural theory of intergroup relations (Blau 1994) and contact theory (Allport 1954) we may reach an opposite expectation would suggest a different causal mechanism. Residential proximity to ASCs may provide the opportunity to interact with asylum seekers (Blau 1994). Intergroup contact, when positive, fosters tolerance (Allport 1954;

Pettigrew and Tropp 2011). ~~This influence of contact~~Hence, positive contact with asylum seekers may make voters less inclined to support the radical right. The influence of positive contact experiences can be explained by induced levels of knowledge, empathy and perspective taking (Brown and Hewstone 2005; Pettigrew and Tropp 2011). According to Allport, superficial contact (i.e. mere exposure) or overt negative contact, like abuse and name-calling would only lead to more trouble (Allport 1954: 263). Intergroup contact would only foster tolerance if contact takes place under ‘optimal’ conditions, like equal group status or common objectives. ~~Yet~~However, Pettigrew and Tropp (2011) convincingly demonstrated in their meta-study that although the effect of intergroup contact is stronger if contact takes place under optimal conditions, commonly, these conditions are not necessary; intergroup contact – at least when not clearly negative – induces tolerance even if Allport’s conditions are not met- (but see also Paluck et al. 2019 who point at a lack of experimental evidence for this claim).

Based on a choice experiment on preferences for refugee and migrant homes, Liebe et al. (2018) conclude that contact with refugees increases acceptance to refugee homes in the immediate vicinity, in line with contact theory. Studies that focused on the impact of intergroup contact on radical right voting seem to provide support for both the positive contact mechanism (Green et al. 2015; Rydgren, 2008; Savelkoul et al. 2017; but see also Savelkoul and Scheepers 2017) and the negative contact mechanism (Nijs, ~~Stark and Verkuyten, et al., 2019) as well).~~ However, the presence of ~~refugees~~asylum seekers in ASCs may not always provide the most favourable opportunities for sustained positive interactions (cf. Dinas et al. 2019). It is thus not self-evidently true that increased proximity to ~~refugees~~asylum seekers leads to more positive contact experiences (cf. Enos 2014), or that it not at the same time leads to more negative contact experiences. That being said, ~~not taking into account we expect, on the positive basis of contact mechanism may obscure a possible theory, that the presumed~~ positive relation between increased local exposure to ~~refugees~~asylum seekers and increased support for the ~~radical right via the~~PVV as a result of feelings of ethnic threat mechanism may be suppressed by increased local positive interethnic contact experiences (Hypothesis 3).

~~In this contribution, we put the threat and positive contact mechanism to empirical scrutiny. We expect that voters who have suddenly become exposed to asylum seekers in their neighbourhood are more likely to support the PVV than their counterparts in neighbourhoods who did not experience a sudden influx of asylum seekers (Hypothesis 1). We expect, on the basis of conflict theory, that changes in support for the PVV as a consequence of increased exposure to asylum seekers may be explained by increased perceptions of local intergroup~~

Formatted: Font: Italic

~~threat (Hypothesis 2a) and, on the basis of contact theory, may be suppressed by increased local positive interethnic contact (Hypothesis 2b).~~

Data and operationalization

IVandaag Opinion Panel

This study employs individual-level panel data from the IVandaag Opinion Panel (IVOP) in the Netherlands. The IVandaag Opinion Panel consists of 50,000 people from all parts of the Dutch population living across the country. People sign up for this online panel of their own. Every week panel members give their opinion on current topics such as politics, economics, health care and crime. The results are announced in the broadcasts of ‘EenVandaag’ on public television and presented to politicians and policymakers. The advisory board of the IVOP consists of Dutch University professors Joop van Holsteijn, Jelke Bethlehem and Tom van der Meer. More information on the panel can be found here (in Dutch): <https://eenvandaag.avrotros.nl/panels/opiniepanel/uitleg/>. For access to the original (anonymized) data we received from IVOP, scholars may contact the owners of the IVOP. ~~The processed datasets (and scripts) on which results of this contribution are based can be accessed through Data Archiving Networked Services (doi: XXX).~~ For the current study we did not access any personal identifying data. Our study does not pose any risk to panel members or their individual privacy and hence we did not deem it necessary to seek approval of Radboud University’s Ethics Committee.

The measures used in this contribution are included in two waves of the IVOP. Because people sign up for this online panel of their own, there is a self-selection bias in the sample of respondents (Bethlehem 2010). However, due to a uniquely large sample size we cover a high degree of the variety of people found within the Dutch population even though some groups (e.g. women, the young, lower educated) are underrepresented in the sample. The first wave of our data was collected in February 2015 and the second wave of our data was collected in November 2015. The period in between the two waves spanned the period in which the high influx of asylum seekers and the subsequent settlement of asylum seekers in residential environments throughout the Netherlands took place (Figure 1). As the focus of our study is on native Dutch individuals, we excluded respondents with a non-native Dutch background from our analyses (N=1,151). We classified respondents as native Dutch when both parents were Dutch, or when respondents identified as being Dutch in case one parent was non-Dutch.

IVOP panel members regularly receive invitations to fill in online questionnaires and can decide whether or not to participate in specific waves. Of the 26,064 native Dutch

respondents who filled out the questionnaire in wave 1, 19,988 respondents also completed the questionnaire in wave 2. There was no significant relationship between ~~being~~becoming exposed to asylum seekers in the local environment, the main focus of our analysis, and the likelihood of participating in wave 2. PVV supporters of wave 1 had a .79 probability to participate in wave 2, non-PVV supporters a .76 probability. This selectively will lead to conservative tests of our hypotheses; we will be less likely to pick up an increase in PVV support over time in our panel data (see Table A1, Appendix).

The neighbourhood identifier included in the 1VOP is the four-digit part of the post code. The median number of residents in these neighbourhoods is 2,645 (mean=4,142) and the median surface area 5.35km² (mean=8.65km²).

Central Agency for the Reception of Asylum Seekers

We enriched our individual-level data with information from the Central Agency for the Reception of Asylum Seekers (COA) about the number of asylum seekers at the neighbourhood-level. COA is responsible for housing asylum seekers from the time they request asylum until they receive a residence permit or must leave the Netherlands. Due to the exceptionally high influx of asylum seekers in 2015, the maximum capacity of existing regular reception centres ('reguliere opvang') was soon reached. COA therefore opened new regular reception centres but also housed asylum seekers in temporary centres ('noodopvang') and, starting from September 2015, also in crisis centres ('crisisnoodopvang'). Regular reception centres are used for at least a period of two years and have a capacity ranging from 300 to more than 1,500 people. Temporary centres were set up in, for example, remodelled market halls or empty office buildings. These centres generally house around 300 asylum seekers and are used for a period of six to twelve months. Various facilities were used as crisis centres, such as sport halls and old school buildings, which were already marked out by local governments to house citizens in times of incidents or disasters. Crisis centres give room to a dozen to several hundred asylum seekers, but only for short periods (in principle up to 72 hours) at a time. Before ~~refugees~~asylum seekers could be housed in crisis centres by COA, the local government needed – in principle – to agree. However, the placement process was chaotic and even for policymakers the procedures and responsibilities were unclear (Ministry of Justice and Safety, 2015).

~~Refugees themselves~~Asylum seekers did not have any say in where they were going to be housed and because we assess changes in voting intention in a relatively short period of time, native residents are very unlikely to have moved out of the neighbourhood as a consequence of

the inflow of ~~refugees~~ asylum seekers. Selective residential mobility plaguing neighbourhood effects research in general (Hedman and Van Ham 2012) is thus unlikely to influence this study's results.

Notwithstanding that protests of the local population were more intense in some places than in others and that some municipal governments displayed a higher willingness to host asylum seekers than others, the increased exposure to asylum seekers was to a large extent an exogenous process for the neighbourhood residents whose voting intention it could affect. Voters of neighbourhoods that would experience an inflow of ~~refugees~~ asylum seekers did not differ with respect to radical right support from voters that would not experience an inflow of ~~refugees~~ asylum seekers: pre-~~crisis~~ crisis support for the PVV for both the 'treated' and 'untreated' groups was approximately 17%. ~~Our empirical study thus comes close to a natural experiment (see also Appendix, Table A3).~~

<<<Figure 1>>>

Changes in support for the PVV

To examine changes in voting intention for the radical right in the Netherlands, we measured respondents' intended voting behaviour at two time points with the following question: 'Which party would you vote for if parliamentary elections were held today?'. The answer categories consisted of the eleven largest political parties represented in the Dutch parliament as well as the option 'another party'. In addition, respondents could also answer 'I don't know', 'blank vote', 'I'm allowed to vote, but I wouldn't', 'I'm not allowed to vote', and 'no answer'. We removed from the analysis the respondents who answered 'I'm not allowed to vote' and 'no answer' in one or both waves (less than 2%). Respondents who answered 'I don't know', 'blank vote', 'I'm allowed to vote, but I wouldn't' could in one of the two waves be politically mobilized or demobilized and experience respectively a shift towards or a shift away from the radical right and are therefore included in our analysis. Voting intention for the PVV is included as dichotomized variable (YES=1 vs. NO=0).

Exposure to asylum seekers

For each ASC we know the exact address. Depending on the type of ASC we received different information from COA. For regular and temporary ASCs we know how many asylum seekers were housed at 1-1-2015 and 15-11-2015. For each crisis centres we know the daily mutations in asylum seekers from 18-9-2015 until 15-11-2015. Before 18 September, asylum seekers were

not housed in crisis centres. The data of COA thus allowed us to capture the change in exposure that took place *after* respondents were interviewed for the first time and *before* respondents were interviewed for the second time. To account for differences in sizes between neighbourhoods, we calculate the number of asylum seekers per 1,000 inhabitants. We acknowledge that the exposure to asylum seekers and the impact of this exposure for voting intentions may depend on the type of ASC asylum seekers were housed in. Native residents living close by regular ASCs may already have been familiarized by the presence of ~~refugees~~asylum seekers (Lubbers *et al.* 2006). This may mitigate the impact of increased exposure on PVV support. ~~Refugees~~Asylum seekers could only live very briefly in the same crisis ASCs (generally up to 72 hours), ~~this~~which will have made it difficult to develop sustained positive interactions with native neighbourhood residents. Especially among neighbourhood residents who have become exposed to ~~refugees~~asylum seekers as a consequence of placement of ~~refugees~~asylum seekers in crisis ASCs, we may therefore expect the threat mechanism to dominate. Thus, besides the measure of total relative exposure to asylum seekers, we also calculate the increase in the number of asylum seekers in regular ASCs, in temporary ASCs, and in crisis ASCs separately.

Ethnic threat and interethnic contact

Feelings of local interethnic threat are measured with the item: 'I sometimes worry about the fact that my neighbourhood deteriorates because of the arrival of ethnic minorities'. The answer categories are: 0. 'totally disagree', 1. 'disagree', 2. 'agree/nor disagree'/'I don't know/no opinion', 3. 'agree', and 4. 'totally agree'. We measure local positive interethnic contact with non-western ethnic minorities with the following question: 'How often do you have personal contact in your neighbourhood with people of non-~~Western~~western descent? By personal contact, we mean that you know the name of this person and occasionally have a conversation with this person.'. The answer categories to this item are: 0. 'never'/'not applicable', 1. 'about once a year', 2. 'several times a year', 3. 'about once a month', 4. 'several times a month', 5. 'several times a week', and 6. '(almost) every day'.

Missing values and working sample

We removed 506 respondents (2.5%) for whom we could not match the contextual information about the exposure to asylum seekers in the local living environment due to missing information on their geographical location. This left us with a working sample of 19,091 respondents in 2,997 four-digit postcode areas (74% of all inhabited postcode areas). Descriptive statistics of

our main variables – based on the final samples used in our analyses – are displayed in Table 1.

~~The descriptive statistics of individual level sociodemographic variables, such as gender, age, and education, will not be publicly disclosed at the request of the owners of the 1VOP panel.~~

Analytical strategy

To test our hypotheses, we employ both fixed effects and hybrid models. In fixed effects models the influence of all time-invariant characteristics are removed, allowing us to assess the net effect of being exposed (more precisely: changes in exposure) to asylum seekers in the local living environment on individuals' changes in voting intentions. The fixed effects analyses are based on a reduced sample of the respondents whose voting intentions changed over time (N=1,389, living in 1,002 neighbourhoods). Fixed effects models tell us what would happen to an individual's voting intention if the exposure to asylum seekers would increase by one unit given that these individuals have changed their voting intention between time point 1 and time point 2. Because voting intentions for the PVV are operationalized as a dichotomous variable, we estimate logistic fixed effects models.

In our hybrid models (aka 'between-within method'), time-varying predictors are decomposed into a between-person component (i.e. person-specific mean) and a within-person component (i.e. deviation from person-specific mean). Time (i.e. wave) is included as fixed-effect. The causal estimates tell us how experiencing a change (e.g. in exposure to asylum seekers) is related to a change in the odds to vote for the PVV. An advantage of this method is that respondents who did not experienced a change in voting intention can also be included. We included additional time-constant controls for neighbourhood 'poverty' (i.e. average house price) and 'percentage of non-western minorities'. The latter naturally excludes asylum seekers. At the individual level, we controlled for the time-constant variables gender, age, and education. Our hybrid analysis are based on the total sample of 19,091 respondents living in 2,997 different neighbourhoods.

We made a detailed replication package (website) for this paper (including datasets, scripts, additional tests; weblink: XXX). It not only allows the interested reader to replicate all our results and claims made in the paper but also to assess the impact of different operationalisations and modelling strategies.

<<<Table 1>>>

Results

Among voters who changed their support for the PVV, voters are far more likely to have voted for the PVV in wave 2 compared to wave 1: among the switchers, 75.88% voted for the PVV in wave 2 (Table 1). In general, support for the PVV increased as indicated by the percentages referring to the hybrid sample: from 16.72% in Wave 1 to 20.48% in Wave 2. Although on average the increase in feelings of threat and intergroup contact experiences are relatively small (0.16 and 0.26, respectively for the fixed effects sample), there is quite some within-individual variation in changes in feelings of threat and contact. As expected, we see that asylum seekers are housed in crisis centres only in wave 2. Among our respondents, approximately 8% experienced an inflow of refugees/asylum seekers in their neighbourhood. This illustrates that although the 2015 refugee crisis was the biggest refugee crisis the Netherlands experienced in recent history, only a relatively small percentage of voters became directly exposed to refugees/asylum seekers in their local neighbourhood environment.

<<<Table 2>>>

Table 2 displays the results based on the logistic fixed effects models. The positive coefficient for Wave 2 indicates that, irrespective of whether residents have witnessed an influx of asylum seekers in their neighbourhood, the odds of voting for the PVV have increased over time ($b=1.118$ $se=0.064$, Model 1, Table 2). On top of this general increase in support for the PVV, people who have suddenly become exposed to asylum seekers as a result of the establishment of an ASC in their neighbourhood are even more likely to switch to the PVV than to switch away from the PVV ($b=0.022$, $se=0.42012$; Model 1, Table 2). This corroborates hypothesis 1. With each unit increase in the exposure to asylum seekers – an increase of one asylum seeker per 1,000 inhabitants – ceteris paribus, the odds for an individual to vote for the PVV increase by 2.2% ($\exp(0.022)$). In Model 2 we break down exposure to asylum seekers by type of ASC. All estimates referring to exposure are positive but only an increase of exposure to asylum seekers housed in crisis centres is significantly related ($p<0.10$, two-tailed) to people's likelihood to vote for the PVV ($b=0.028$, $se=0.017$; Model 2, Table 2). That said, the coefficients of all three types of ASCs do not significantly differ from one another: LR $\chi^2(2)=1.31$.

With Model 3, we test the threat mechanism. In line with conflict theory, we find that people who experienced an increase in feelings of ethnic threat are more likely to have switched to the PVV ($b=0.268$, $se=0.058$; Model 3, Table 2). With one unit increase in ethnic threat, the odds for a single individual to vote for the PVV increase by 31% ($\exp(0.268)$). Increased

positive contact with non-western minorities is not significantly related to PVV-voting (Model 4, Table 2) and thus also does not suppress the threat mechanism. Including ethnic threat and contact into our explanatory model simultaneously does not substantially alter the estimates of exposure to asylum seekers (estimates referring to exposure are almost identical across Model 2 and Model 5). Neither increased threat nor contact is more common among residents who experienced increased exposure to asylum seekers than among residents who did not experience an increase in exposure to asylum seekers. There was a significant difference in changes in contact for voters who did not experience an inflow of refugees/asylum seekers ($M=0.296$, $SD=2.164$) and voters who did ($M=-0.198$, $SD=2.190$); $t(129.37)=2.285$, $p=0.024$ but in the opposite direction as expected. There was no significant difference in changes in threat for voters who did not experience an inflow of refugees/asylum seekers ($M=0.170$, $SD=1.113$) and voters who did ($M=0.108$, $SD=1.170$); $t(127.89)=0.534$, $p=0.594$. T-tests performed on fixed-effects sample. Thus, notwithstanding that heightened perceptions of ethnic threat are an important explanatory factor for changes in PVV support, we therefore refute both hypotheses 2a2 and 2b3.

The results of our hybrid models are summarized in Table 3. Results referring to the main variables of interest – exposure to asylum seekers – led to identical conclusions as described above, even though the estimates are smaller than the estimates produced by the fixed effects models, as expected (Allison 2009). A change in total exposure to asylum seekers is significantly ($p<0.10$, two-tailed) related to the odds to vote for the PVV: with each unit increase in the total exposure to asylum seekers the odds to vote for the PVV increases slightly by 0.1% (Model 1). Holding all covariates at their mean, for female voters who did not experience an inflow of refugees/asylum seekers the probability to vote for the PVV after the crisis was 13.4%, for female voters who experienced an inflow of 100 refugees/asylum seekers per 1,000 neighbourhood residents the probability was 15.1%. For their male counterparts the estimated probabilities are 21.6% and 24.1%, respectively (predicted probabilities based on estimates as summarized in Table 3, Model 1). The impact of increased exposure (change in probabilities of 1.7% for women and 2.5% for men) is substantial in comparison to the general trend in increased support for ‘non-treated’ voters; increased probabilities of 2.7% for women and 4.0% for men.

The estimates referring to exposure to asylum seekers housed in specific typetypes of ASCs are positive but no longer reach significance (Model 2). When voters’ feelings of threat increased ($b=0.117$, $se=0.020$, Model 3) and, surprisingly, when positive contact with non-

western immigrants increased ($b=0.018$, $se=0.007$, Model 4), their support for PVV increased as well. As can be seen in Model 5, taking into account whether or not people experienced an increase in contact with non-western immigrants did not affect the threat mechanism. Thus our hybrid models also confirm hypothesis 1 and refute hypotheses 2a2 and 2b3.

The estimates referring to the time-constant (between) predictors are in line with previous research (cf. Savelkoul et al. 2017). Most importantly, voters with higher mean levels of threat are more likely to vote for the PVV ($b=1.414$, $se=0.023$, Model 3). Voters who have more positive contact with non-western immigrants in their neighbourhood are less likely to vote for the PVV ($b=-0.058$, $se=0.010$, Model 4). The (between-level) estimates referring to exposure to asylum seekers are not significant. This is a clear indication that the placement of ASCs has been exogenous to people's (pre-crisis) party preference, as we claimed.

<<<Table 3>>>

Robustness checks

If people's voting intentions change, they mainly change within the left-wing bloc consisting of Labour (PvdA), GreenLeft (GL) and the Socialist Party (SP) or within the right-wing bloc consisting of liberal-conservatives (VVD), Christian-democrats (CDA) and the PVV (Van der Meer et al. 2015). An exception is the exchange between the PVV and the SP, which are both considered to be populist, anti-establishment parties (Bakker et al. 2015; Immerzeel et al. 2016).

It could be that the PVV lost votes to other parties of the right-wing bloc and won votes from the anti-establishment party SP (or vice-versa), thereby obscuring the general trend of increasing PVV popularity. Moreover, volatility patterns could differ between people who did and did not become exposed to asylum seekers in their neighbourhood in 2015. This may explain in part our small and/or non-significant estimates for our exposure measures reported above. As a robustness check, we therefore also ran multinomial fixed effects models (Table A1A2, Appendix; voting intention for the PVV is now the base category). It turns out that during the refugee crisis, the PVV was especially successful in attracting voters from the other anti-establishment party (i.e. SP), as indicated by the estimate of 'wave 2' referring to the odds 'Anti-establishment vs. PVV' ($b=-2.008$, $se=0.105$; this estimate differs significantly from the estimate of 'wave 2' referring to the odds 'Other Parties vs. PVV': LR $\chi^2(1)=294.87$). Of our exposure measures, only 'exposure to asylum seekers in crisis centres' reaches significance and only for the odds 'Right wing vs. PVV' and 'Other parties vs. PVV'. However, all estimates referring to 'exposure to asylum seekers in crisis centres' are negative and do not significantly

differ from one another. The impact of exposure to [refugeesasylum seekers](#) does not depend on pre-crisis voting intentions (cf. Karreth *et al.* 2015).

Several scholars have suggested that the impact of increasing diversity on related concepts such as prejudice may depend on, for example, residents [authoritarianauthoritarian](#) values (Velez and Lavine, 2017), national rhetoric (Hopkins, 2010), or the initial share of outgroups (Newman, 2013). Because this contribution is interested in the average impact of increased exposure to [refugeesasylum seekers](#), because even with our impressive dataset, still relatively few neighbourhoods faced an inflow of [refugeesasylum seekers](#), and because our survey lacked measures of most likely potential moderators, we did not formulate hypotheses on the conditional impact of exposure to [refugees.asylum seekers](#). That said, in additional analyses using our hybrid models, we tested for an interaction between initial levels of ethnic density (i.e. percentage of non-western minorities) and increases in exposure to [refugeesasylum seekers](#) but these did not reach significance ([results-upon-requestsee replication package](#)).

In line with most previous research on the impact of the ethnic composition of the neighbourhood and support for the radical right, we operationalized exposure to [refugeesasylum seekers](#) as relative group size, in this case, the number of [refugeesasylum seekers](#) per 1,000 neighbourhood residents. For crisis centres, our exposure measure refers to the average number of asylum seekers for the days that the centre housed asylum seekers. To try to capture the time heterogeneity in exposure to [refugeesasylum seekers](#) housed in crisis centres, we multiplied the number of days [refugeesasylum seekers](#) were housed in each crisis centre (range: 1 - 41) with the number of [refugeesasylum seekers](#) at that specific day (range: 20 – 420). To take into account differences in neighbourhood size, this score was divided by the number of neighbourhood residents (per 1,000). The Spearman's *rho* statistic between the original exposure measure and this alternative operationalization was .53. The alternative operationalization of exposure to [refugeesasylum seekers](#) in crisis centres did not reach significance in our additional analyses (Table [A2A3](#), Appendix). This may indicate that exposure to more [refugeesasylum seekers](#) is more likely to fuel support for the radical right but that longer exposure to [refugeesasylum seekers](#) may dampen this effect, possibly due to a familiarization process (cf. Lubbers *et al.* 2006). In line with this idea, we observe that the estimated impact of the number of days [refugeesasylum seekers](#) were housed in crisis centres on PVV support was negative ($b=-0.113$; $se=0.043$), and, once we control for differences in time use between crisis centres, our original exposure measure becomes stronger ($b=0.64$; $se=0.025$; Table [A2A3](#), Appendix). Binary exposure measures (yes/no increase in [refugeesasylum seekers](#)) did not reach significance (Table [A2A3](#), Appendix). This

operationalization of exposure may simply be too blunt and our non-significant findings may indicate that it is not so much whether refugees asylum seekers were housed in one's neighbourhood but about how many refugees asylum seekers entered the neighbourhood.

As stated above, because people sign up for the IVOP online panel of their own, there is a self-selection bias in the sample of our respondents. As a robustness check we repeated our fixed effects analysis on a weighted sample (based on sex, age and educational level). For this weighted sample, we find that both exposure to asylum seekers in temporary ASCs and crisis ASCs is related to an increase in support for the PVV (Table A3 and A4, Appendix).

We argued above that our study comes close to a natural experiment; voters who experienced an inflow of refugees asylum seekers (the treatment) were similar to voters who did not experience an inflow of refugees asylum seekers. With our individual-level panel data we were already able to take unobserved time-stable heterogeneity into account. With a natural experiment, unobserved time-varying heterogeneity (including pre-treatment trends in PVV support) is not likely to have biased our results. However, we acknowledge that group differences may have occurred by chance and that the distribution of refugees asylum seekers may not have been perfectly random. As a robustness test, we therefore used a nonparametric pre-processing matching approach on the sample which we used to estimate our fixed effects models. We used a binary treatment variable (increase in exposure = 1) in the matching procedure. The pre-treatment covariates on which we perform a nearest neighbours match are: age, gender, education, threat, contact, ethnic density in neighbourhood and socio-economic status of the neighbourhood. Matching our data leads to a somewhat stronger estimated impact of exposure to asylum seekers in crisis ASCs (Table A2A3 and A3A5, Appendix).

Following the suggestion of an anonymous reviewer, we also estimated a Difference in Differences estimator. The traditional DiD model for individual-level panel data with additional time-constant covariates c_i is:

$$Y_{it} = \beta_1 Time_t + \beta_2 Treat_i + \delta(Time_t \cdot Treat_i) + c_i + \epsilon_{it} \quad (1)$$

with δ being the DiD estimator and $Treat_i$ the dichotomous treatment variable and Y_{it} the continuous outcome variable. Formula (1) is equivalent to:

$$\Delta Y_i = \beta_1 + \delta \cdot Treat_i + \epsilon_i \quad (2)$$

Since our outcome is a binary variable there is no standard DiD model. Our main results reported in Table 2 are therefore based on the following model:

$$\text{logit}(\text{Pr}(\Delta Y_i = 1 | \text{Treat}_i)) = \beta_1 + \delta \text{Treat}_i, \quad (3)$$

with $\Delta Y_i = 1$ if the dependent outcome was 1 post-treatment (i.e. wave 2) and 0 if the dependent variable was 1 pre-treatment (wave 1). Our Treat_i variable is the change in exposure the asylum seekers. Formula (3) is the fixed effects logistic regression model for two waves (or, more precisely, the first difference model which for two waves is equivalent to the more general fixed effects model). Note, that respondents who did not change support for the PVV drop out of this analysis. Because we have a binary outcome and we use a nonlinear link function we cannot interpret δ as the DiD estimator. Moreover, our original ‘treatment’ variable is not a dichotomous variable, and this also makes why we cannot interpret our effect as the traditional DiD estimator. To be able to interpret our effect as a DiD estimator, we estimated formula (1) directly for a binary outcome variable as an additional robustness check (on our complete sample of panel respondents). That is, we estimated a linear probability model (LPM), while controlling for heteroscedasticity in the error term. We did this once with our original continuous ‘treatment’ variable and once applying a dichotomization. To avoid any possible post-treatment bias we did not include our time-varying contact or threat measures. We estimated models with and without time-stable covariates. We summarized the DiD estimators in Table A6 (Appendix). The DiD estimators based on binary treatment variables do not reach significance. Above we already observed that it is not whether the neighbourhood experienced an inflow of asylum seekers but how many asylum seekers entered the neighbourhood (Table A3, Appendix). The DiD estimators based on continuous treatment variables reached significance (albeit only in models without additional covariates) in line with our results reported in Table 2 and Table 3.

Conclusion and discussion

In 2015 an unprecedented number of asylum seekers had to be housed in existing and haphazardly created new (temporary and crisis) asylum seekers centres. Our large-scale individual-level panel data on voting intentions provided us with an unique opportunity to expand academic knowledge about the ~~causal~~ relationship between the influx of asylum seekers in the local environment and support for the radical right. During the refugee crisis support for the radical right increased and especially among people who experienced an increase in exposure to asylum seekers in their neighbourhood (~~cf. Dinas et al. 2019~~). In the Netherlands, people appear to be receptive of abrupt, rapid and visible increases in the number of immigrants, which might coincide with a ‘not-in-my-back-yard’ syndrome (Ferwerda, ~~Flynn and Horiuchi~~

et al., 2017). Based on several robustness analyses, we tentatively conclude that larger inflows of ~~refugees~~asylum seekers in the neighbourhood (relative to the group size of native residents) fuel support for the PVV, at least in the short run. When ~~refugees~~asylum seekers stay in the neighbourhood for longer, this impact may be curbed (Lubbers *et al.* 2006). We encourage scholars to replicate our findings, preferably in different countries.

We tested our hypotheses employing individual-level panel data allowing us to control for (time-stable) unobserved heterogeneity. Given the short time-window between our survey waves, selective residential mobility did not plague our study. Moreover, exposure to asylum seekers was to a large extent random and our study therefore resembled to some extent a natural experiment. Because of these three reasons, combined with the fairly consistent results over different modelling strategies, many data and model requirements are met to give a causal interpretation to our finding that an inflow of asylum seekers into the neighbourhood is related to an increase in radical right support in this neighbourhood. However, we need to acknowledge that a natural experiment is not a true experiment and that our estimates only reached the boundary of the conventional significance criteria.

War refugees are considered to be more deserving to enter and stay in the Netherlands (cf. Bansak *et al.* 2016) than ‘classical migrants’. Consequently, the impact of similar unexpected sharp increases in the size of migrant populations in neighbourhoods that result from union formation and labour migration on radical right voting may be ~~even~~ larger. Naturally, these latter migration flows are generally less volatile than migration flows as a result of a humanitarian crisis and this may explain why previous research only observed small effects of changing migrant sizes in neighbourhoods on radical right voting (e.g. Savelkoul *et al.* 2017).

This study is one of the first to demonstrate the previously established threat-radical right relationship (e.g. Lucassen and Lubbers 2012; Werts *et al.* 2012) from a longitudinal perspective; residents ~~who experienced increased feelings of local interethnic threat~~whose worries about neighbourhood deterioration resulting from migration increased during the refugee crisis were more likely to start expressing intentions to vote for the PVV. Even though our results thus confirmed that increasing feelings of local ethnic threat are an important driving force for support for the radical right, this could not explain why especially residents of neighbourhoods in which asylum seekers were housed became more likely to vote for the PVV. This is because an inflow of asylum seekers did not increase feelings of neighbourhood deterioration. We need to acknowledge that our single-item threat measure did not explicitly refer to economic, cultural or safety issues in the neighbourhood because of the inflow of asylum seekers. With a better (multi-item) measurement instrument we may have picked up the

assumed relation between the inflow of asylum seekers and increased feelings of ethnic threat. However, our null finding, is in line with previous studies, using different measures of ethnic threat.

It could be the case that not necessarily anti-immigrant attitudes increased as a result of the influx of asylum seekers but that already previously held (negative) opinions regarding immigration became more salient in these neighbourhoods. This resonates with the idea of Karreth *et al.* (2015) that increasing diversity is only related with negative attitudes towards immigrants among people on the political right. At the national level, the share of the Dutch population that mentioned immigration as one of the two most important issues facing the Netherlands at the moment increased between February 2015 and November 2015 from 9% to 56% (European Commission, 2015a; 2015b; own calculations). Heightened issue salience is likely to increase the relative importance that voters attach to this issue. A promising direction for future research would therefore be to assess the role of (increased) issue saliency in the link between (increased) local outgroup size and support for the radical right.

We expected that increased positive contact with minorities would mitigate the impact of increased exposure to asylum seekers on radical right voting. In line with contact theory, we observed that voters who have more contact with non-western minorities are less likely to vote for the radical right as compared to voters with less contact with non-western minorities. Unexpectedly, at the same time we observed that residents who experienced an *increase* in positive interethnic contact during the refugee crisis became more likely to express support for the radical right; the estimates referring to the between and within effects of interethnic contact were opposite in direction. Increased positive interethnic contact did not suppress the threat mechanism. As contact opportunities may lead to both positive and negative contact, it may be that the same voters who experienced an increase in positive contact also experienced an increase in negative contact and that the impact of negative contact experiences on voting intentions was more severe. A recent study showed that negative contact experiences predict support for the PVV, even after controlling for indicators of threat (Nijs *et al.* 2019).

Political parties had to come clean during the refugee crisis as to their position on the immigration issue in general and as to their position on whether and where to house asylum seekers in particular. The VVD (next to the PVV the main anti-immigration party) definitely showed colours by making it perfectly clear that to limit the influx of even more refugeesasylum seekers it was willing to endorse the EU-Turkey agreement (i.e. the ‘refugee deal’). This may explain why the PVV was not especially successful in attracting new voters from the VVD during the refugee crisis. Instead, we demonstrated that especially former voters for the Social

668 Party (SP) were likely to switch to the PVV. Volatility patterns are thus clearly context
669 dependent. The SP shares the radical right's anti-establishment rhetoric, but as owner of the
670 issue of immigration (Kleinnijenhuis and Walter 2014) the radical right used its anti-
671 establishment rhetoric to successfully capitalize on the convergence of the immigration and
672 anti-establishment issue during the 2015 refugee crisis at the expense of the Socialist Party.

673 The radical right gained support in the Netherlands during the 2015 refugee crisis and
674 especially among residents who were exposed to asylum seekers 'in their backyard'. Why this
675 is so remains unclear; the threat mechanism does not seem to hold. We encourage scholars to
676 test two alternative ideas we could unfortunately not test ourselves: the negative contact
677 mechanism and the issue salience argument.

Letter of explanation

We would like to thank all reviewers for their comments and for their time invested in thoroughly reading our manuscript. It is nice to see our manuscript is appreciated, valued and sparks a scientific debate.

In our opinion, the paper became stronger after incorporating reviewers' comments and suggestions.

We made a replication package (website) for this paper (including datasets, scripts, additional tests). This website is currently hosted from the GitHub repository of the first author. We send the link of the replication website to the editor for inspection. Naturally, the Editor/PlosOne is free to share the link with the reviewers even if this would mean anonymity can no longer be ensured. We hope this replication package will contribute to the scientific debate on the impact of inflow of asylum seekers on support for the radical right and on different modelling strategies when faced with a 'natural experiment', a continuous 'treatment variable', a dichotomous outcome variable and individual-level panel data.

Reviewer #1: Title: Exposure to Asylum Seekers and Changing Support for the Radical Right

This paper tests how the sudden inflow of asylum seekers to a region changes voters' support for the radical right in the region. Unlike many other studies on the support for the radical right, this paper utilizes an individual-level panel dataset on the regional level, employs a natural experiment method, and distinguishes between different types of refugee centers. Though authors' finding that the inflow of asylum seekers strengthens the support for the radical right is not surprising, their methodological approaches contribute to the literature. Though I support the publication of this manuscript, there are some questions that should be answered beforehand.

1. The structure of the hypotheses is odd. Hypothesis 1 describes the positive correlation between refugee inflow and support for the PVV. Then, the two hypotheses (2a and 2b) suggest two different causal mechanisms between the two: one for the positive correlation (threat) and the other for the negative correlation (contact). I do not deny that the inflow of asylum seekers, or immigrants in general, can have dual effects (both positive and negative) through threat and contact mechanisms either on the support for the radical right or on public opinion on immigrants. Nonetheless, I think authors need to re-frame their hypotheses so that they incorporate all of these possible mechanisms and patterns.

Following the suggestion of R#1 we reframed our hypotheses. We hope to have made more clear that the threat mechanism is likely to mediate the expected positive relation and that the positive contact mechanism is likely to suppress the expected positive relation. Thus, we expect a positive relation between the inflow asylum seekers and support for the PVV (Hypothesis 1) and this is in part explained by the threat mechanism (Hypothesis 2). Recognizing that the inflow of asylum seekers can have dual effects, we expect that increased local positive interethnic contact experiences as a result of the inflow of asylum seekers can suppress the positive relation between the inflow of asylum seekers and increased support for the PVV (Hypothesis 3). (see section 'Theoretical expectations')

2. Related to the first comment, authors find and conclude that their results support H1, but not H2a and H2b. That is, though they find a positive correlation between refugee inflow and PVV support, the causal mechanisms they hypothesized are not supported by the results. Then, the question is: WHY does the refugee inflow strengthen support for the radical right? Authors need to discuss this.

The reviewer is right that the threat (and positive contact) mechanism does not explain regional variation in changing support in PVV support. The question is “Why, at the local level, refugee inflow strengthen support for the radical right?”. In the revised manuscript we expanded the original discussion. An inflow of asylum seekers into the neighbourhood may not necessarily change the valence or strength of anti-immigration attitudes but their salience. We also mention the negative contact mechanism: the inflow of asylum seekers may have increased negative intergroup contact within the locality and, consequently, support for the PVV. Unfortunately, measures for issue salience and negative contact were not present in our dataset. A possible reason may also be our less ideal threat measure. See also point 3 below. (see page 18 of revised manuscript)

3. Though authors distinguish economic threat and cultural threat in their theory section, their threat variable doesn't. I understand that authors were not able to change the survey question, but they need to provide more discussion on the question wording itself. When the question was delivered to respondents, did it imply economic threat, cultural threat, or both of them to the people?

The reviewer is right; our threat measure does not explicitly tap into economic, cultural or safety threat. The wording of our threat measure was: “I sometimes worry about the fact that my neighbourhood deteriorates because of the arrival of ethnic minorities.” We assume that when respondents evaluate the possible deterioration of their neighbourhood they will consider possible economic, cultural and safety issues. Following the suggestion of the reviewer we address the limitation of our threat measure in the revised discussion section. [see page 19]

That being said, in the Social and Cultural Developments in the Netherlands survey of 2018 (<https://doi.org/10.17026/dans-2dz-9wvy>), the same neighbourhood threat item was part of a larger set of threat items tapping into economic and cultural threat. In this dataset among 828 native Dutch respondents, the neighbourhood threat item correlates positively with cultural and economic threat items: ‘The coming of ethnic minorities to the Netherlands is a threat to our own culture’ ($r = .659$); ‘I sometimes am afraid that my financial prospects will decline due to the presence of ethnic minorities’ ($r = .649$). We think this warrants our assumption that our neighbourhood threat item will also pick up, to some extent, feelings of economic and cultural threat. However, we think it is beyond the scope of the present contribution to incorporate a rigorous discussion of item validity by employing a different dataset.

4. As authors acknowledge, one critical weakness of their data is a plausible self-selection bias because respondents basically voluntarily sign up for the survey. One question related to this is: is there possibility that PVV supporters, after the sudden inflow of asylum seekers, are more motivated to accept the invitation to the survey in the 2nd wave because of, for example, their anger from the inflow? If this is true, then the self-selection bias problem occurred and it could make their results biased toward their findings. So, is there any way to make sure that

PVV supporters and non-supporters had the same propensity to sign up for the survey, both in the 1st and the 2nd wave?

*Following the suggestion of reviewer#1, we investigated the possibility that PVV supporters in wave 1 are more motivated to accept the invitation to the 2nd survey than non-PVV supporters. We would like to point out that if this type of selection occurred, our results will be biased **against** our findings, because we are then less likely to observe an increase in PVV support between wave 1 and wave 2 (because of an inflow of asylum seekers) due to a ceiling effect. We indeed observe some significant selectivity; PVV supporters of wave 1 have a .79 probability to participate in wave 2, non-PVV supporters a .76 probability. This selection thus leads to conservative tests of our hypotheses. [see page 9]*

Whether respondents of wave 1 experienced an increase in exposure to asylum seekers did not predict participation in wave 2, neither did an interaction between PVV support in wave 1 and increase in exposure to asylum seekers. Thus experiencing a 'treatment' is not related to selective participation. Receiving a treatment is also not related to pre-crisis PVV support.

5. Authors describe three different types of refugee centers on page 11, but I don't believe that they explained what a temporary ASC is. (Does the "crisis ASCs" on line 320 actually mean temporary ASCs?)

We explain the three different types of refugee centers in paragraph 'Central Agency for the Reception of Asylum Seekers'. Page 9, line 259 and further. We did mean 'crisis ASC' on line 320.

Regular reception centres ('reguliere opvang'): long-term (minimum lease contract 2 years). Most regular reception centres already existed before the 2015 refugee crisis. Temporary centres ('noodopvang'): mid-term (buildings are generally leased for a period of six to twelve months). Crisis centres ('crisisnoodopvang'): short-term (no minimum lease period). The same refugees are housed in crisis centres for a maximum of 72 hours.

Reviewer #2: This is an interesting paper on how the sudden inflow of refugees influenced vote intentions in the Netherlands. The strength of the paper is the possibly exogenous exposure to refugees due to the rapid inflow, combined with individual level panel data. The authors find that exposure to refugees increased the vote intention for PVV, the anti-immigration party in the study.

1. My main issue with the paper is how they analyze the data. The current analysis makes me not convinced that the authors estimate the effects of exposure.

The first issue regards exogeneity. The authors have a clear ambition to estimate causal effects, but is not sufficiently clear on what variation in exposure to refugees that is exogenous. Clearly, between-unit variation in exposure is not exogenous, but part of the variation between the waves might be exogenous. To me, the most promising source of exogenous variation stems from the crisis ASC, and the paper and the analysis should be centered on that source of variation.

We fully agree with R#2 that the within-unit variation over time in exposure to asylum seekers is most interesting. This is exactly why we estimate FE models and why we focus on the

within-effects when we discuss the results of our hybrid model. We argue that it is (very) likely that the within-unit variation over time in exposure to asylum seekers is to a large extent exogenous because: (1) respondents did not have time to move between the survey waves; (2) asylum seekers could not decide where they were housed; (3) the Dutch government and COA did not have time to select neighbourhoods for new temporary centres nor have time to select crisis centres (4) experiencing an inflow of asylum seekers was not related to pre-crisis PVV support.

We fully admit that even if we assume that there was no active selection by respondents, asylum seekers or institutions of the neighbourhoods in which asylum seekers could be housed, this not fully guarantees that all variation in changing exposure to asylum seekers is exogenous. But because we use individual-level panel data we already control for time-stable unobserved heterogeneity (either by estimating a FE model or by including relevant time-stable variables into our hybrid model). This only leaves us with possible unobserved time-varying heterogeneity in exposure. Although, PVV supporters in wave 1 were more inclined to participate in wave 2 than non-PVV supporters (see R#1 comment 4) experiencing an increase in exposure of asylum seekers was not related to participation in wave 2 (not for PVV-supporters and not for non-PVV supporters). This makes one source of unobserved time-varying heterogeneity (different time trends in voting intentions between respondents who experienced an increase in exposure to asylum seekers) less likely but not impossible.

We also agree with R#2 that whether or not a change in exposure to asylum seekers may be assumed to be exogenous may depend on the type of ASC. We are, however, unsure for which type it is most likely to be exogenous. Our guess would be this will refer to changes in asylum seekers housed in the regular ASC which did not yet reach full capacity before the 2015 refugee crisis. R#2 would guess exogenous changes will be most likely associated with crisis centres, probably because these locations were already marked out by local governments to house citizens in times of incidents or disasters. We therefore show the impact of total exposure, and the impact of exposure to asylum seekers for each type of ASC separately.

We discuss the issue of the extent to which variation in exposure to refugees can be assumed to be exogenous in several places in the manuscript. We also come back to this issue in the discussion.

We have the ambition to estimate a model by which it is most likely that estimates refer to causal mechanisms. We stress in our manuscript that thanks to our data and modelling strategy it is more likely that our estimates refer to causal mechanism than related research in which no individual-level panel data is used and in which selection effects are more likely. We do not claim to have estimated causal mechanism and we try to refrain from causal language in our manuscript. We use sentences like “An influx in asylum seekers is related to a change in support of the PVV.” to describe our results. See also page 19 of our revised ‘conclusion and discussion’ paragraph:

“

We tested our hypotheses employing individual-level panel data allowing us to control for (time-stable) unobserved heterogeneity. Given the short time-window between our survey waves, selective residential mobility did not plague our study. Moreover, exposure to asylum

seekers was to a large extent random and our study therefore resembled to some extent a natural experiment. Because of these three reasons, combined with the fairly consistent results over different modelling strategies, many data and model requirements are met to give a causal interpretation to our finding that an inflow of asylum seekers into the neighbourhood is related to an increase in radical right support in this neighbourhood. However, we need to acknowledge that a natural experiment is not a true experiment and that our estimates only reached the boundary of the conventional significance criteria.

”

We hope that R#2 agrees with us that our estimates are more likely to represent true causal mechanisms as compared to related previous research (see also reaction to comment 2 below).

2. This leads me to the second issue which regards the analysis. I think the authors should estimate a standard differences-in-differences model using the crisis ASC as the treatment indicator (equal to one if a crisis ASC was set up in the neighbourhood between wave 1 and 2) and the wave as the post-treatment indicator. The DD estimate from this analysis might be given a causal interpretation.

Reviewer 2 recommends us to "estimate a standard differences-in-differences model using the crisis ASC as the treatment indicator (equal to one if a crisis ASC was set up in the neighbourhood between wave 1 and 2) and the wave as the post-treatment indicator".

The traditional DiD model for individual-level panel data with additional time-constant covariates c_i is:

$$Y_{it} = \beta_1 \text{Time}_t + \beta_2 \text{Treat}_i + \delta(\text{Time}_t \cdot \text{Treat}_i) + c_i + \epsilon_{it} \quad (1)$$

with δ being the DiD estimator and Treat_i the dichotomous treatment variable.

Formula (1) is equivalent to:

$$\Delta Y_i = \beta_1 + \delta \text{Treat}_i + \epsilon_i \quad (2)$$

Since our outcome is a binary variable there is no standard DiD model. We therefore estimated:

$$\text{logit}(\Pr(\Delta Y_i = 1 | \text{Treat}_i)) = \beta_1 + \delta \text{Treat}_i, \quad (3)$$

with $\Delta Y_i = 1$ if the dependent outcome was 1 post-treatment (i.e. wave 2) and 0 if the dependent variable was 1 pre-treatment (wave 1). Note, that respondents who did not change support for the PVV drop out of this Fixed Effects Logistic regression analysis. Our Treat_i variable is the change in exposure to asylum seekers. Formula (3) is the fixed effects logistic regression model for two waves (or, more precisely, the first difference model which for two waves is equivalent to the more general fixed effects model).

Formula (2) demonstrates that the DiD model is a type of fixed effects model because the time constant covariates drop out of the model. With our FE-model, we are thus able to control for time-stable unobserved heterogeneity. This, together with the fact that within unit-variation in our treatment can be assumed to be to a large extent random (which we show in our manuscript), we can make strong (but not definite!) claims on causality.

Naturally, we are aware that because we have a binary outcome and we use a nonlinear link function we violate the common trend assumption necessary to interpret delta as the DiD estimator. Moreover, we like to point out that our original ‘treatment’ variable $Treat_i$ is not a dichotomous variable, and this also makes why we cannot interpret our effect as the traditional DiD estimator. But we do not claim to estimate a DiD estimator.

Following the suggestion of R#2 we estimated formula (1) directly for a binary outcome variable as an additional robustness check. That is, we estimated a linear probability model (LPM), while controlling for heteroscedasticity in the error term. We did this once with our original continuous ‘treatment’ variable and once applying the dichotomization as suggested by the reviewer. For the latter model, the estimate could now be interpreted as a DiD estimator.

Given the comment of Reviewer#2 on post-treatment bias below we estimated the models without including our measures for contact and threat. We estimated models once with and once without the time stable covariates. The full results of all these additional DiD analyses can be found in our replication package. We summarized results with respect to the DiD estimator in Table A6. The DiD estimator based on a binary treatment variable did not reach significance but this was expected given the results presented in Table A3 in which the binary treatment variable did not reach significance either. The continuous treatment variable reached significance in the models without covariates, in line with our results based on the fixed effects logistic regressions.

3. This again leads me to the third issue which is the examination of “as-if-random” exposure to refugees. The balance analysis in the paper (Table A3) is not properly explained. The appropriate way to examine balance is to conduct an F-test of whether the exogenous covariates can jointly predict the treatment. For instance, if you use the setup of crisis ASC in the respondents as the treatment you need to show that treated neighborhoods are similar to comparison neighborhoods.

In our understanding of the literature there are quite a lot of different ways how to test for unbalance and how to take this into account. We would like to mention that we could distinguish four different ‘treatments’ (‘total inflow’, ‘inflow into regular ASCs’, ‘inflow into temporary ASCs’ and ‘inflow into crisis ASCs’) which are continuous treatment variables and not dichotomous.

The reviewer suggest us to conduct an F-test of whether the exogenous covariates can jointly predict the treatment. In this approach it is usually recommended to include many functions of the observed covariates (higher order terms and interactions). However, naturally, the F-test will be significant (at least for some model specifications and for some specific operationalization of our treatment variable) given our sample size and relatively few ‘treated’ respondents. We followed the strategy to reduce imbalance in our data, simply accepting that our dataset is to some extent unbalanced on key variables. Note that we provided the means of covariates for the pre- and post-matching datasets (Table A5). We

observe that most difference of means between treatment and control groups decreased (and the treated and untreated groups are now of equal size). When we reduce imbalance, effects of interest become stronger (indicating some downward bias in the original dataset) and remain significant (even with increased variance in our estimates as a result of selectively pruning observations during the matching procedure).

Once again, we like to point out that we made a full replication package on GitHub. We have send the link to the editor, who is free to share this with the reviewers even if by this anonymity can no longer ensured. Would this manuscript be accepted for publication, it is very straightforward to replicate all tables and appendices and to try different matching strategies.

4. The fourth issue is how the authors threat the contact and threat variables. To me these variables should be analyzed as outcomes that are potentially affected by exposure, they should not be analyzed as covariates (see the literature on post-treatment bias). I understand that the authors considers them as mechanisms or mediators, but one needs separate exogenous variation to properly estimate the role of mediators. Or, if the authors are willing to make strong (and in my view implausible) assumptions, they conduct a Baron-Kenny-type of mediation analysis.

We did analyse these outcomes which may be potentially affected by increased exposure to asylum seekers. We mention in the manuscript that changes in exposure are NOT related to more threat or contact (see page 14). Hence the threat mechanism cannot mediate the impact of exposure and the positive contact mechanism cannot suppress the impact of exposure. For a (Baron-Kenny-type) analysis of mediation, the independent variable (change in exposure) should predict the mediator (change in threat and contact).

We understand post-treatment bias as (unnecessary) controlling in the regression model for the consequence of the treatment. However, our main results are summarized in Table 1 and Table 2. These tables summarize models in which threat and contact are not included (Models 1 and 2) and in which threat and contact are introduced in a stepwise fashion (Models 3-5).

In the requested DiD analysis (comment 2) we did not include our measures of threat and contact.

[We continued the numbering of R#2's minor points]

5. The attrition analysis mentioned on page 9 should be reported in the appendix.

We followed the suggestion of the reviewer and added an appendix, Table A1.

6. The underrepresentation of different groups (pg 9) should be presented in the appendix.

At the request of the owners of the IVOP dataset the descriptive statistics of these demographic variables for our total sample are not included in the main manuscript. See page 8/9: "For access to the original (anonymized) data we received from IVOP, scholars may contact the owners of the IVOP." But see comment 7 below.

7. Also, are sample weights applied?

We added a robustness check on a weighted sample (see revised Table A3) and provided descriptive statistics on the weighted variables with respect to our FE sample (Table A5). We reach substantially similar conclusions using a weighted sample.

8. The authors are probably interested in the experimental literature on contact theory, reviewed in Paluck et al. (2019, The contact hypothesis re-evaluated, Behavioural Public Policy)

We thank reviewer for the interesting article. We refer to Paluck and colleagues' study on page 8 of our revised manuscript.

9. Have they considered non-linearity in the relationship between exposure and vote intention, perhaps exposure has larger effects in neighborhoods with low prior exposure (e.g. Hopkins 2010, cited in the paper)?

Please note that our main model is already a non-linear model (logit link function) and that exposure to asylum seekers resulting from temporary and crisis centres pre-crisis is simply zero. We show in the manuscript that "The impact of exposure to refugees does not depend on pre-crisis voting intentions (cf. Karreth et al. 2015)." (see page 16). We also mention that "we tested for an interaction between initial levels of ethnic density (i.e. percentage of non-western minorities) and increases in exposure to refugees but these did not reach significance (see replication package)." (see page 16).

Reviewer #3: This is a very important study. The effect to contact with asylum seekers on support for radical right-wing populist parties is an important subject to study. This is not the first study to examine this, but it is a very rigorous study. In this field, in particular given the social relevance of this research (how do values like tolerance develop, what is the societal reaction to refugees) and academic relevance in the debate between contact and threat, I think that studies like these, which rigorously look at the effect of specific events are welcome. In particular I think this contributions stands out because of their advanced quasi-experimental design, which is apt to study the phenomenon, well-executed and convincing.

Thank you.

1. I have only very minor concerns. The first of these is that there is a typo on p.13: it now reads concerning the main effect studied in the paper "(b=0.022, se=0.12; Model 1, Table 2)" but then the effect would not be significant. This has to be (b=0.022, se=0.012) in line with the Table 2.

We corrected the typo.

2. The second is that the paper mixes the terms refugees and asylum seekers while the first term refers to people who have an official status as refugee and these second term refers to people who want that status. That means that in COA centres there only are asylum seekers and no refugees (who get their own housing once their status has been given).

We thank reviewer#3 for pointing out this inconsistency. We changed the label refugee to asylum seeker whenever we explicitly mean the persons living in Dutch ASCs. See also page 5 where we explain our use of the terms refugee and asylum seekers.
